MICROSCOPY.

Royal Microscopical Society.

MEETINGS FOR 1882,

AT 8 P.M.

THE "SOCIETY" STANDARD SCREW.

The Council have made arrangements for a further supply of Gauges and Screw-tools for the "SOCIETY" STANDARD SCREW for OBJECTIVES.

The price of the set (consisting of Gauge and pair of Screw-tools) is 12s. 6d. (post free 12s. 10d.). Applications for sets should be made to the Assistant-Secretary.

For an explanation of the intended use of the gauge, see Journal of the Society, I. (1881) pp. 548–9.

ADVERTISEMENTS FOR THE JOURNAL.

Mr. CHARLES BLENCOWE, of 75, Chancery Lane, W.C., is the authorized Agent and Collector for Advertising Accounts on behalf of the Society.

COUNCIL.

ELECTED 8th FEBRUARY, 1882.

PRESIDENT.

Prof. P. Martin Duncan, M.B., F.R.S.

VICE-PRESIDENTS.

Prof. F. M. Balfour, M.A., F.R.S.
Robert Braithwaite, Esq., M.D., M.R.C.S., F.L.S.
Robert Hudson, Esq., F.R.S., F.L.S.
John Ware Stephenson, Esq., F.R.A.S.

TREASURER.

Lionel S. Beale, Esq., M.B., F.R.C.P., F.R.S.

SECRETARIES.

Charles Stewart, Esq., M.R.C.S., F.L.S.
Frank Crisp, Esq., LL.B., B.A., V.P. & Treas. L.S.

Twelve other MEMBERS of COUNCIL.

Ludwig Dreyfus, Esq.
Charles James Fox, Esq.
James Glaisher, Esq., F.R.S., F.R.A.S.
J. William Groves, Esq.
A. de Souza Guimaraens, Esq.
John E. Ingpen, Esq.
John Mayall, Esq., Jun.
Albert D. Michael, Esq., F.L.S.
John Millar, Esq., L.R.C.P.Edin., F.L.S.
William Thomas Suffolk, Esq.
Frederick H. Ward, Esq., M.R.C.S.
T. Charters White, Esq., M.R.C.S., F.L.S.

I. Numerical Aperture Table.

The "APERTURE" of an optical instrument indicates its greater or less capacity for receiving rays from the object and transmitting them to the image, and the aperture of a Microscope objective is therefore determined by the ratio between its focal length and the diameter of the emergent pencil at the plane of its emergence—that is, the utilized diameter of a single-lens objective or of the back lens of a compound objective.

This ratio is expressed for all media and in all cases by $n \sin u$, n being the refractive index of the medium and u the semi-angle of aperture. The value of $n \sin u$ for any particular case is the "*numerical aperture*" of the objective.

Diameters of the Back Lenses of various Dry and Immersion Objectives of the same Power (¼ in.) from 0·50 to 1·52 N. A.	Numerical Aperture. ($n \sin u = a$.)	Angle of Aperture (= 2 u).			Illuminating Power. (a^2.)	Theoretical Resolving Power, in Lines to an Inch ($\lambda = 0.5269\,\mu$ = line E.)	Penetrating Power. ($\frac{1}{a}$)
		Dry Objectives. ($n = 1$.)	Water-Immersion Objectives. ($n = 1.33$.)	Homogeneous-Immersion Objectives. ($n = 1.52$.)

	0·50	60° 0′	44° 10′	38° 24′	·250	48,200	2·000

EXAMPLE.—The apertures of four objectives, two of which are dry, one water-immersion, and one oil-immersion, would be compared on the *angular* aperture view as follows:—106° (air), 157° (air), 142° (water), 130° (oil). Their actual apertures are, however, as ·80 ·98 1·26 1·38 or their numerical apertures.

TRANSACTIONS OF THE SOCIETY.

X.—*On some Micro-organisms from Rainwater-Ice, and Hail.*
By R. L. MADDOX, M.D., Hon. F.R.M.S., &c.

(Read 10th May, 1882.)

THE study of the minute organisms belonging to the Schizophytes is one of special interest, for they touch the final history of all living beings, and very possibly hasten, if they do not actually cause, premature death. The researches within late years by very able microscopists and members of the medical profession have been numerous, though far from exhaustive. They embrace almost every field of inquiry, as the valuable Summary in the pages of the Journal of the Society so well attests; hence, some one may have preceded me in similar observations, as ice, hail, snow, rain, and dew have each been often examined; I am not aware, however, that the points I have to mention have been specially noticed; and I therefore trust they may not be wholly devoid of interest, even in their incompleteness.

The winter of 1880–81 was of considerable severity from the extreme cold, which if already forgotten, allow me to recall to memory, by stating the fact that at my residence, one day whilst at dinner, with a good fire in the room, water when poured into a tumbler immediately became a mass of beautiful ice-crystals. The out-of-door temperature for several days was such, that the rain-water in the open garden rain-water butt was frozen to the depth of more than 12 inches. When the thaw occurred, I placed a large block of the ice, after *well draining*, in a clean new pan, and removed it into the house, set it in a fireless room, and covered it carefully from the dust. Three days later I noticed a thin scum extending over the entire surface of the water in the butt, and at once put some on a slide and examined it with the Microscope. It was found to be a mass of micro-organisms lying in a pellicle intermixed with particles of soot, dust, and a few minute oily-looking

globules.   The organisms differed from any I have ever noticed
before or seen figured in any papers treating on Bacteria.   Slides
were prepared, some without staining the objects, others by staining
with aniline blue, and much later on were photographed, using a
$\frac{1}{8}$-inch objective and artificial lamp-light.   The exposure upon the
(commercially so called) " instantaneous " gelatino-bromide plates
varied from four to five minutes.   The negatives, from deficiency
in actinic power of the light employed, were too thin to furnish fair
paper prints; hence they were copied upon wet collodion into
positives, and these by the same procedure into denser negatives
with some enlargement compared with the originals.

The micro-organisms in the pellicle, as seen under the Micro-
scope, appeared as minute rods or joints very irregularly shaped,
and most of them larger at one end than the other, being either
club-shaped or like the handle of a pistol, possibly due to the
formation of a spore at that end, though this is doubted by some,
for many had lying upon or near to the thick end a round or oval
body, as if it had escaped from the adjacent rod.   Some of the little
bodies tapered gradually from the thick end.   Where the placing
of the pellicle on the thin cover-glass had not much disturbed its
condition, the organisms were seen to lie very generally side by
side, though not evenly, and in more or less slightly curved lines,
as if the growth had been in a longitudinal direction upon a
gentle curve, yet not giving rise to the sharper curve seen in many
of the rods forming the mass.   Amongst the numerous figures
given in the 'Annuaire de l'Observatoire de Montsouris,' for the
last three years, by M. Miquel, of the various micro-organisms
he has found in the air by daily systematic observation, I have not
noticed one similar to the one described.   Besides these organisms
there were a few small bodies in the pellicle, looking like ordinary
bacteria and micrococci; but the general mass in the scum con-
sisted of the large forms.   Their size varied considerably, the large
ranging from the $\frac{1}{6000}$ to $\frac{1}{5000}$ of an inch, and the small of the same
kind, to little more than half this length.   Whether these bodies
should be placed in the Schizophytes as Bacteria or Bacilli, I was
doubtful, as more experienced observers than myself differed in
opinion.   No movement was seen in those freed from the broken
edge of the pellicle.   The difference in shape from the ordinary
Bacilli rods might have been due to hindrance in their development
from the previous severe cold, though if confirmed in future
observations, it may be of a specific character.

The block of ice removed to the pan, furnished on the third day
a pellicle which was much thinner, but contained exactly similar
rods.   There was considerably less contamination.   The same was
examined at different periods, and after remaining undisturbed for
more than thirteen months showed the rods to differ but little from

the original ones; being rather straighter, the club or pistol-handle shape still very evident, and the rods in somewhat more regular position. From the result of my rough cultivation experiments I am inclined to regard them as Bacilli. A few cultivations were attempted with the pellicle from the water-butt, also from the pan. For instance, I tried to cultivate them in sterilized (i. e. by boiling) normal urine, in sterilized infusion of Liebig extract of meat, upon cold boiled potatoes and the white of hard-boiled egg, without increased temperature beyond that of a fireless room, but with no positive success. Yet eight months later a speck taken from the pellicle, removed with some of the water from the butt at the time of the original observation, carefully kept covered and undisturbed, and which contained the club-shaped rods in abundance, when placed on sterilized gelatine jelly prepared with infusion of Liebig extract of meat, showed ready growth in the rods, some to more than twice their original length, others multiplying into short joints. In the long ones the characteristic irregularity of outline was apparent in very many. The growth from two minute specks placed one at each end on a layer of the jelly, poured on a scrupulously clean slide, soon covered in length the intervening distance of an inch. Curiously, they were more or less arranged in circular groups, the centre being often occupied with a beautiful rosette of some salt crystal, though the individual rods were without regular arrangement, the short rods crossing each other in all directions. After such an interval it would be hazardous to say they were all derived from the club-shaped rods. What I wish to note is, that *they* grew into longer ones, so to establish their claim to be placed amongst the Bacilli. Later still, in the month of April this year, some of the same pellicle was sown on peptonized gelatine jelly without any evidence of the growth of the rods, and at the same date some placed on hard-boiled white of egg offered no change discernible, though in both cases there were very many minute organisms, as bacteria and micrococci, in Brownian movement. I may note that Mr. M. A. Veeder, U.S.A., found that various infusoria, confervæ, &c., in the sediment of the clearest parts of blocks of ice from stagnant water of ponds and canals, would revive when melted, and considers such ice doubtful for drinking purposes.

I will now pass to some remarks on the micro-organisms found in melted freshly-fallen hail.

A rather heavy hailstorm happening on the 25th of last March, I took the opportunity to collect some of the hail for examination while the storm continued, by dipping a perfectly clean tumbler into a drifted heap lodged in one corner of the window-ledge, without touching anything else; immediately covering the tumbler with a clean plate of glass, and allowing the hail

to melt in a room without a fire. On the second day a faint scum was visible on the surface in patches, enveloping grey, soot-like particles. Some of this pellicle seen under the Microscope showed very pale, motionless organisms lying in it, resembling rather elongated micrococci. The water was left further undisturbed for another day, but furnished no appreciable difference except greater distinctness of the imbedded organisms. Some of the pellicle was stained with aniline blue, and mounted in acetate of potash solution without having been dried. Whether from want of refractive differentiation between the objects and mounting medium, or from the acetate of potash acting upon the pellicle, the outlines of the minute organisms were indistinct; consequently a different method was adopted, which seemed to offer advantages. A speck of the pellicle was placed, with as little disturbance as possible, in a droplet of distilled water on the cover-glass, then, as recommended by different observers, dried over a flame, in this case very slowly. Afterwards it was covered with the following staining fluid and protected from the dust : —

Bismarck or aniline brown (of German make), 4 grains; citric acid, 16 grains; distilled water, 200 minims; boiled in a test-tube, cooled, filtered, reboiled, and a trace of carbolic acid added.

After being covered with the staining medium for an hour it was washed with distilled water by tipping off the fluid, draining closely on blotting-paper, repeating this until the water was colourless, then drying again by gentle heat and mounting the cover dry.

Previously I tried the aniline brown without the citric acid, but the addition of the latter appeared to facilitate the washing by increasing the solubility of the colouring agent without lessening the staining qualities.

Great care was required if the specimens were washed with the cover on the slide, for the least displacement caused the pellicle with its organisms to roll up into continuous lines.

I am not prepared to say that the method of drying does not slightly shrink the objects. I fear it does, though I do not think more than osmic acid, as the substance enveloping the organisms appears indistinctly afterwards. The minute bodies found in the melted hail differed most completely from those of the frozen rain-water. In parts where but little disturbance of the pellicle occurred upon removal for examination, the organisms were seen lying very irregularly near to each other, whilst in what appeared to be a *second* pellicle formed just beneath the outer one, they occurred mostly in rows, and are often at rather an acute angle with one another. In size they differed, doubtless owing to being in various stages of growth and fission.

The average size is from the $\frac{1}{21000}$ to the $\frac{1}{15000}$ of an inch in length; some looked round, others like elongated micrococci, and when fission was about to occur very like ordinary bacteria. As they were when free motionless, I felt inclined to suppose them to be micrococci, but from some cultivation experiments I believe they must be termed bacteria.

Thus a speck of the pellicle was placed on freshly boiled white of egg, and kept carefully covered and turned down without touching anything except by the broken shell edge. The second day, about thirty-six hours after the inoculation, on removing a minute portion and diluting it with distilled water, it presented an incredible crowd of bacteria in rapid motion, resembling closely, if not actually, *Bacterium termo.* On the sixth day the white of egg, at the spot of inoculation and for some distance beyond, presented a beautiful pale canary-yellow colour, and on the eleventh day a bright deep rose-coloured spot also appeared, very closely to the seat of puncture, consisting of motionless micrococci. This has been successfully cultivated through several generations on the same medium.

A portion of the original pellicle placed on peptonized gelatine jelly on the thin cover, and this placed over a tin cell cemented to an ordinary slide, the surface of the tin circle being smeared with vaseline (as recommended, I believe, by an American microscopist), except at two small opposite points, and then kept at the temperature of about 58° F., had on the second day so softened the gelatine by the changes induced in it, that the spot of inoculation was quite fluid, teeming with minute organisms in most rapid motion; hence, as several inoculations were made, and with like results, I conclude that chiefly bacteria and only few micrococci existed in the hail in a quiescent or resting stage, and when supplied with proper nutriment and more favourable conditions, the organisms, suited to the circumstances, quickly turned from the quiescent state to one of the greatest activity. Of course I do not pretend there may not have been different varieties in the hail, for the organisms of rain-water have been found to determine butyric, lactic, ammoniacal and putrefactive fermentation; but what appears to me probable is, that one if not more amongst the organisms supported the temperature, whatever that might have been, that determined the formation of hail, remaining in an almost quiescent state, for I believe the Bacteria have their resting stage, and that the more advantageous conditions of nutriment and temperature speedily determined activity. The general mass of the jelly remained free from visible change. Before actual fluidity of the material occurred, close to the inoculated spot, numerous small, round, grey, finely granular, ascococcus-looking

patches made their appearance, and gradually coalescing, joined the edge of the inoculation. Of their nature I can say nothing definite. How they came there is rather puzzling, seeing none formed in other parts of the jelly.

At the same time, and in a similar manner, the same nutrient medium was inoculated with a speck of the old pellicle from the ice in the pan: the club-shaped rods did not, at this date and in this medium, undergo any visible change; but some of the minute organisms showed development, though not to any great degree, only exhibiting Brownian movement, whilst some of the same pellicle placed on the boiled white of egg at the same time as the former experiment with the pellicle from the hail, furnished on the second day minute organisms which, when seen in a droplet of distilled water, were not very active; but the club-shaped rods, if they multiplied, did so to an indiscernible extent. There was no chromogenous change at the point of inoculation, as with the pellicle from hail.

The minute organisms found in the melted hail-water scum, were no doubt derived from the rain-drops congealing round the air-borne dust-particles to which they were adherent, and afterwards slowly multiplied afresh on the surface of the melted hail. Some have doubted whether bacteria form part of the atmospheric dust; but the very careful experiments and cultures of M. Miquel, at the Montsouris Observatory, tend to prove that such bodies are suspended in the air and to be constantly found in rain, hail, and snow. Numerous figures are given. To avoid contamination in culture experiments, when objects are only for a short time exposed to unfiltered air, is a great source of difficulty. M. Miquel remarks in the 'Annuaire,' published this year, that snow, usually regarded as the great air-purifier, is not so in reality, for although it largely attracts the bacteria it meets with in its passage, it does not fix them like moistened earth; as a sudden squall cutting into the snow will often again bear them aloft. January and February have furnished him with the minima; October and November with the maxima in the gatherings. Cold he places the first, and extreme dryness the second agency in the destruction of atmospheric bacteria. Rainfall much lessens their number, whilst this again rises upon the succeeding dryness. He finds them ten times more numerous in the centre of Paris than in the country, for the same volume of air, and he gives the proportional numbers as, micrococci 93, bacilli 5, bacteria 2, for the first, and micrococci 79, bacilli 14, bacteria 7, for the second. He also furnishes the mean for the different months. The micrococci are pretty constant, the bacilli highest in April, May, July, and August, and lowest in November, January, and June; the bacteria nil in January, February, and June, and highest in the month of May.

The difficulty is to find a suitable medium for nourishing or rejuvenating all the aerial germs that have been gathered by the aspirator.

The great extremes of heat and cold to which the spores of many of the Schizophytes have been exposed without loss of vitality is a point of much interest. The Rev. Mr. Dallinger, in his careful experiments, found the death-points in dry heat, for the mature monads that he had studied, to range from 138° F. to 142° F., but their spores supported for five to ten minutes 250° to 300° F.; whilst the same heated in fluid were destroyed at 212° to 268° F. M. Van Tieghem found some micrococci and bacilli to flourish at 74° C. M. Miquel cultivated one form from the Seine at 70° C., which died when the temperature was raised to 72° C. Professor Frisch finds that the bacteria seen in diphtheritic exudation and in puerperal fever resist a *minus* temperature of 87·5° C. without destruction, and the bacilli spores to resist extremes of cold better than the rods. M. Miquel states that a particular *Bacterium* found in snow resisted a temperature of 26° to 30° C. below freezing for three hours, and for more than twenty days a mean temperature below zero of 2·5° C. The enumeration of such experiments might be greatly multiplied.

Drs. Cohn and Mendelsohn state that it required a powerful galvanic battery current of five elements to destroy the vitality of the bacteria they experimented upon.

Not to quote more largely, it seems quite incomprehensible that such minute organisms should be able to resist such extremes of temperature, and that the so-called mucous, gelatinous, albuminoid, cellulose, or by whatever name it may pass, covering, which is permeable to fluids, should be able to defend the living contents against such extraordinary variations of heat and cold. Here, under the hand of most careful experimenters, the reasonableness of previous doubt must give place and credence to the senses. Can it be that the envelope that surrounds the organism normally, when subjected to dry heat, dries so entirely and rapidly as to prevent the entire loss of moisture from within, or that the encapsulation, so to speak, is so perfect, that there is no room for the generation of high-pressure steam, and that under moist heat the coagulation is so effective that it shrinks the outer material so closely upon the contents, that steam cannot be generated except under rupture? Or can the rapid chemical changes they can effect, suffice to continue their vitality under such abnormal conditions?

We may largely theorize, though I fear only to record our ignorance, when we attempt to limit the manifestations of life by predeterminate lines, derived from the study of higher organisms, though amongst these there are some, as the Aphides, stated to

resist extreme cold, and in the case of seeds and chestnuts they are said to have survived the exposure to the very low temperature of −100° C., and very lately in experiments by Messrs. de Candolle and Pictet the refrigeration was carried to − 80° C., the seeds germinating afterwards. I think experiments have also been made on hybernating animals, but I do not remember the exact temperature destructive of life. The minuteness, however, of the Bacteria almost forbids comparison with the other objects.

Such details I fear must be sadly wearying to those who take no special interest in the study of these micro-organisms, and to such I offer every apology. Nevertheless, I would ask them to try and estimate carefully the value of the study of these ubiquitous objects. They set up minute changes in some of the articles of our dietary as either invite or repel the organs of smell and taste. The numerous varieties found by M. Duclaux in the imperfect making of Cantal cheese, at once point to a large field of inquiry among the articles that are in our daily diet. They play a vast rôle as the grand scavengers in the silent destruction of lifeless forms and are thus beneficent agents; they are the companions of our life and accompany, if they do not originate, many depressing and fatal diseases, multiplying so rapidly in cases of lowered vitality of their host that they kill by their numbers, or perhaps by depriving the nutrient fluid of part of its oxygen, though this, as pointed out by Mr. Dowdeswell in his excellent article upon Septicæmia,* seems, in the smaller forms at least, improbable. The chemical changes induced by their own requirements may furnish noxious matters detrimental to the life of the higher organism—and harmless forms under new conditions may perhaps acquire such virulent properties, that in the state of spores the minutest quantity suffices when inoculated into the connective tissue of a healthy animal, if such have not acquired previous immunity, to cause severe illness if not certain death. Their importance, as affecting, on a vast scale, the life of man and of animals, invests them at least with the symbol of respect.†

It is only by cultivation that we can hope to distinguish the living from the lifeless, for may we not have before us in such as are gathered from the air, some that are dead, and some of what Dr. Phipson calls " fossil forms." Morphologically their resemblances may be so great that their differences are to our powers otherwise indistinguishable. Possibly some may be inert when cultivated in one fluid, and highly poisonous in another—as in living bodies.

* Quart. Journ. Micr. Sci., xxii. (1882) p. 66.

† M. Miquel found by the statistics of the mortality that occurred last year at Paris, that there were nine rises which closely corresponded each to a rise in the number of Schizophytes found in the air. He merely points out the interesting coincidence.

The necessity for a certain amount of the poisonous material to be introduced or acquired in the system to produce on the one hand immunity, or on the other hand fatal effects,—the alteration some undergo by exposure to air,—the re-acquirement of highly virulent properties after having had them lessened by culture, may, perhaps, point to the very variable results exhibited in contagious maladies, and malarial fevers, under similar exposures; some receiving the contagium, so to speak, at its first offer, others resisting for lengthened periods.

In the case of malarial fevers there are some points that furnish material for future study.   I will mention an instructive case that came under my notice many years since.   In the neighbourhood of Constantinople, and especially at the Dardanelles, malaria was endemic.   *Assuming* malarial fever to be consequent upon the introduction into the system of the *Bacillus malariæ* of Klebs and Tomassi-Crudelli, this point for inquiry arose.   A sailor had had at one of the ports in the East Indies a first and severe attack of intermittent fever, from which he speedily recovered, and remained free from any recurrence for thirteen years, although visiting various localities where such fevers were common; yet the same night that his vessel anchored, during the day, in the Golden Horn, he was seized with a severe attack of malarial fever, which necessitated his entry into the hospital.   None of the officers or crew suffered similarly, though remaining many days at anchor. Are we to suppose the germs of the former malady remained quiescent in the system for the period of thirteen years, and that a few hours in a suitable locality sufficed to set them into activity and develope a return of the ague; or was he an individual very susceptible to malaria?   I scarcely think so, as he was free at other ports where the malady was common.   Again, should the second attack be supposed as unrelated to the first, under the assumption that he in some way imbibed the malaria in passing the Dardanelles, and that the incubation took three or four days to develop itself, or was it that out of all the places he had visited in the course of his voyages for thirteen years, this locality was the only one to furnish the necessary conditions for a return of the original malady, he being previously in good health?

In the malignant form, in the neighbourhood of the Dardanelles, I have known individuals die in the cold stage within sixteen hours.   Had such imbibed a really toxic quantity of the malarial poison—I am expressly assuming the correctness of the *Bacillus malariæ* theory, which Dr. Sternberg, U.S.A., finds reason to doubt —and did the organisms multiply in such a short period throughout the system or in some vital organ as to thus speedily terminate life without any reaction, under every effort that time permitted?

Mr. E. L. Moss, Staff-Surgeon R.N., found, after forty-eight

hours, by ingeniously contrived experiments, organisms in the blood drawn from intermittent fever patients which he could not find in the fresh blood. It is questionable whether they were the same as the *Bacillus malariæ.*

Dr. Marchiafava contends for the correctness of the statements of Klebs and Tomassi-Crudelli, for he finds the blood of all parts of the body, in those stricken with malarial fever, to contain in the initiative or cold stage both barren and spore-bearing rods, and in the hot or fever stage, only free spores.

The cyclical course of various infectious diseases is attributed by Dr. Wernich and Professor Salkowski, from their careful experiments, to the destruction of the micro-organisms in the living body by their own products, i. e. they are destroyed by their own excreta.

What the term of life may be for the spores of these lowly forms awaits inquiry. The germs of *Bacillus anthracis* are said by M. Pasteur to have survived a period of twelve years, but how much longer, lies in the investigations of the future.

The medical digression has been purposely made to try and engage some of the waste microscopical energy of the members of this Society by showing that complex phenomena attributed to the action of such micro-organisms yet wait for intelligible and satisfactory answers. There is one hint I would throw out to those who need the stimulus of patient work, viz. to follow up the researches of M. Chappuis, by watching the effect of ozone upon the life of the Schizophytes. Such an inquiry may lend light to the obscurity that now veils some of the depressing catarrhal epidemics, such as influenza, &c.

Although much has already been accomplished, much has to be repeated. As yet we only touch the edge of this vast field for research. In it stands a complex problem for those to solve who have the time and patience to compete for even a fractional part. Fortunately encouragement comes from the important experiments now made in other countries, in the form of "preventive inoculation," from which, already, highly beneficial results have been achieved, conservative both to life and to the pocket. May we not apply to ourselves what has been so ably said by Dr. Burdon Sanderson in his recent Lectures upon Inflammation? "We are all of us, old and young, too apt to forget how slow and gradual is the process by which we come to a right understanding of objective facts. Let us be prepared to give equal credit to the past and the present, accepting what is new without losing sight of, much less rejecting, what is old."

[Since the foregoing was written, that indefatigable observer Dr. Koch has discovered another of the Bacteria which he, followed by Dr. Baumgarten, considers as the cause of tuberculosis—a disease

which is responsible for about one-seventh, if not more, of the deaths of our population. Dare we hope that further experimental research may ultimately arrive at some method of diminishing this frightful annual loss? Shall we get a clearer insight into what we term the law of heredity? Supposing infection ab utero, has it no limiting period of incubation? must all ages bend to its presence? I am not aware whether the organisms found in fowl cholera have as yet been discovered in the newly laid egg. The answer can only come from careful experimental inquiry. In it lies the hope of discovering the means of immunity, and I trust that, in spite of hasty and prejudiced legislation, such researches may yet be made in this country, as will conduce, not alone in this, but in other maladies, to the future welfare of both man and beast, so that we may say in the words of the poet :—

> " 'Tis worth a wise man's best of life,
> 'Tis worth a thousand years of strife,
> If thou canst lessen, but by one,
> The countless ills beneath the sun."]

XI.—*The Relation of Aperture and Power in the Microscope (continued).**

By Professor Abbe, Hon. F.R.M.S.

(*Read 14th June,* 1882.)

II.—*The Rational Balance of Aperture and Power.*

The discussion of Part I. relates to one and the same matter, viz. that from all points of view which come under consideration in the use of the Microscope, a certain *proportion* of aperture to power is the necessary basis of perfect performance.

The question we have now to consider is: whether it is possible to arrive at a more definite determination of that proportion than is furnished by the preceding somewhat general discussion of the question of wide and narrow apertures, and in particular, whether that can be done in such a way as to establish a rational standard for the *practical* construction of the Microscope. So far as I know, this matter has not yet been the subject of any kind of regular discussion, though it will be admitted, I presume, by every microscopist to be one of great practical importance. I have now directed my attention to it for more than ten years, not purely from theoretical points of view only, but by means of a long series of practical trials in which I had the advantage of the co-operation of Dr. C. Zeiss, of Jena, and I propose therefore to point out here the principles which, in my opinion, furnish an approximate standard for determining the proper balance of aperture and power in the Microscope.

For this, two distinct questions must be treated separately.

First, the relation of aperture to power must be considered in regard to the *entire Microscope* and we must ascertain what amplification of the ultimate image of the Microscope is useful, or necessary, for every given aperture, and conversely, what aperture is required for the proper utilization of a given amplification. If the subject admits of a scientific discussion at all, it must be possible to indicate the proper relation of aperture and amplification without having regard to the particular manner in which a given amplification is obtained by the co-operation of objective and eye-piece, provided, of course, that the amplification is obtained with the *best* possible quality of the image.

The second question is, what division of the entire power of the Microscope between the objective and ocular will fulfil the condition of a perfect image under a given amplification. This relates essentially to the practical aim of the discussion—the determination of the *focal length of the objective* which is required for the utilization of a given aperture.

* The paper (received 11th April) is written by Professor Abbe in English.

i. *Relation of Aperture to Power in regard to the entire Microscope.*

. 1. The first question may be dealt with under these two heads :—(*a*) What are the smallest dimensions of microscopical detail which are within the reach of any given aperture ? (*b*) What visual angle is required for the distinct recognition of details of given dimensions ? If these can be answered in a reliable manner, the first question will have been disposed of.

The smallest dimensions which are within the reach of a given aperture are indicated with sufficient accuracy by taking the limit of the resolving or separating power of that aperture for periodic or *regular* structures, i. e. the minimum distance apart at which given elements can be delineated *separately* with the aperture in question. The numerical expression of that minimum distance is

$$\delta = \tfrac{1}{2}\frac{\lambda}{a},$$

where *a* denotes the numerical aperture and λ the wave-length of light ; a fair average is obtained for the latter element (with observations with the eye and white light), by taking $\lambda = 0 \cdot 55 \, \mu$ $= 0 \cdot 00055$ mm. ; i. e. the wave-length of green rays between the lines D and E, very near to the point of maximum visual intensity in the diffraction spectrum.

Though this expression applies in strictness only to the visibility of periodic structures composed of regularly arranged elements, it may be taken as an *approximate* measure of delineating power in general, i. e. in regard to *structures of every composition.* My theoretical investigations and experiments show that with objects of *every* shape and arrangement, the microscopical image will not present any indications of structure, the dimensions of which are perceptibly below the value of δ, given (for any aperture) by the above formula. Prominences of any shape on the outline of a coarser object, for example, will disappear more and more as their dimensions approach the value of δ for the aperture in use. Isolated elements of triangular, or quadratic, or rectangular figure will look more and more *alike* (becoming more and more circular or elliptical in form), as they diminish in size to the value of δ.* The loss of diffracted light attendant upon the limitation of the pencils by the lens-opening, changes or obliterates those details which are beyond the limit of the resolving power. Consequently the microscopical image of an object of any composition whatever, will always be *dissimilar* to the object to the same extent ; and the limit of resolving power therefore indicates the limit of *similar* or *correct* delineation generally.

* I have verified these theoretical inferences, for small apertures, by many experiments, with objects of very different nature.

Hence every aperture is fully utilized when the amplification of the entire Microscope is sufficient for a distinct and convenient observation of details corresponding to the value of δ. Lower amplifications would not exhaust the aperture, because indications of *real* structure which exist in the image, would remain hidden from the eye. Higher amplifications, on the other hand, will not promote the recognition of the objects, because all the indications of minuter scale which they might perhaps display, do not exist in the objects, but belong to the image *only*—they are simply modifications of the image due to the aperture in use. Such higher powers would therefore afford nothing more than an exaggeration of those features of the image which are not conformable to the real nature of the object.

We have now therefore reduced the problem under consideration to the single question: What amplification is necessary and sufficient in order to display the δ of every aperture, under that visual angle which is required for distinct vision?

The facts of observation which are within the reach of every microscopist, afford all necessary data for an *approximate* determination of this amplification. The striation of an ordinary specimen of *Pl. angulatum* becomes visible to a very sharp-sighted eye under an amplification of 150 diameters. As the closeness of the lines is about $0 \cdot 5 \mu$ (50,000 to the inch) they are thus recognized under a visual angle not much exceeding 1′ of arc. But *distinct* and *convenient* observation for an average eye will in any case require a much higher power; *how* much higher, will of course vary with different individuals. I am, however, sure to leave sufficient latitude for personal diversities in assigning 300 and 600 diameters as the limits of *useful* amplification for details of these dimensions. In observing the diatom, no one, I presume, will deny the advantage of increasing the power if it is below 300; and on the other hand, no one will admit any further advantage in going beyond 600, provided the observation is made with an aperture not exceeding $0 \cdot 6$, which shows the striæ, *but nothing more.*[*]

It may be inferred from this example, in accordance with many similar facts, that satisfactory observation requires that the smallest detail of the microscopical image shall be displayed under a visual angle of not less than 2′ and not more than 4′, approximately; angles which correspond very nearly to the amplifications 300 and 600 for dimensions of $0 \cdot 5 \mu$.

This admitted, we obtain at once the number of diameters which are required for properly utilizing any given aperture. If a dimension δ is to be displayed under a visual angle of *v* minutes of

* Much higher powers may of course be utilized in the observation of *Pl. angulatum* with objectives of wide aperture. In this case, however, the image contains indications of form upon the markings of much minuter dimensions.

arc, the necessary amplification, N, for a distance of 250 mm. or 10 inches (1′ being $= 1 : 3438$) is

$$N = \frac{250}{3438} \cdot \frac{v}{\delta},$$

and substituting for δ its equivalent in terms of the aperture $\left(\dfrac{\lambda}{2a}\right)$ we obtain the general formula :—

$$N = \frac{250}{3438} \cdot \frac{2\,a\,v}{\lambda};$$

or, if λ is taken $= 0 \cdot 00055$,

$$N = 264 \cdot 5 \, a\,v.$$

By introducing into this formula $v = 2'$ and $v = 4'$ respectively we obtain the figures of *useful* amplification for a series of different apertures as shown in Table I.—useful, that is, so far as *delineating power* is concerned, putting aside for the moment any question as to the *illumination* of the object, which, as explained hereafter, allows of somewhat greater apertures.

TABLE I.

Aperture.	Aperture-Angle (air).	δ, Measure of the least attainable Detail.	N, Amplification for obtaining a Visual Angle of	
			$v = 2'$	$v = 4'$
	°	μ		
0·05	5·7	5·50	26	53
0·10	11·5	2·75	53	106
0·15	17·2	1·83	79	159
0·20	23·0	1·37	106	212
0·25	29·0	1·10	132	265
0·30	35·0	0·92	159	317
0·35	41·1	0·79	185	370
0·40	47·2	0·69	212	423
0·45	53·5	0·61	238	476
0·50	60·0	0·55	264	529
0·55	66·7	0·50	291	582
0·60	73·7	0·46	317	635
0·65	81·1	0·42	344	688
0·70	88·8	0·39	370	741
0·75	97·3	0·37	397	794
0·80	106·3	0·34	423	846
0·85	116·4	0·32	450	899
0·90	128·3	0·31	476	952
0·95	143·6	0·29	503	1005
1·00	180·0	0·27	529	1058
1·05	..	0·26	555	1111
1·10	..	0·25	582	1164
1·15	..	0·24	608	1217
1·20	..	0·23	635	1270
1·25	..	0·22	661	1323
1·30	..	0·21	688	1375
1·35	..	0·20	714	1428
1·40	..	0·19	741	1481
1·45	..	0·18	767	1534
1·50	..	0·18	793	1587

Conversely we can obtain the aperture a, which is sufficient for the utilization of a given power of N diameters, provided a visual angle v' is required for the least detail within the reach of that aperture. This is given by the formula

$$a = \frac{N}{264 \cdot 5} \cdot \frac{1}{v}.$$

Table II. shows the values of a corresponding to different amplifications under the supposition of a visual angle $v = 2'$; it exhibits, therefore, the *maximum* aperture which can be admitted as useful for any given power under the above assumptions. The assumption of any other visual angle as necessary for distinct vision of the least detail, would change a in the inverse proportion of v, so that for $v = 1'$ we should have twice the figures of a given in the second column of the table, and for $v = 4'$ one-half.

TABLE II.

N, Amplification for 250 mm.	a, Aperture for a Visual Angle of the least detail, $v = 2'$.	Aperture-Angle (air).

500	0·945	141·8
600	1·134	
700	1·323	
800	1·512	
900	1·701	
1000	1·890	

Though these figures cannot of course pretend to be more than an approximation to the actual requirements under various given conditions, yet they will indicate with sufficient accuracy the *limits* of useful power; in that the delineating power of any given aperture cannot be fully utilized when the number of diameters (obtained *with a really good quality of the image*) is *much* below the minimum figures of the table; and that, on the other

hand, we shall have an *empty* amplification, which does not improve the representation of the objects, if the power should go *much* beyond the maximum figure.

The salient fact suggested by the two tables is the relatively *low* figures of amplification which are sufficient for very wide—in particular for the widest—apertures; and, conversely, the small apertures which are sufficient for the low powers of the Microscope. I do not, of course, intend to assert that, under particular circumstances and for particular purposes, much higher figures of amplification than are shown in the tables may not be very useful or even necessary; as, for instance, for counting, measuring, drawing, &c. What I wish to convey is, that in the present state of the Microscope they are not required and are not even advantageous, for *research*, i. e. for the proper *recognition* of the objects. A visual angle, for the minutest elements of a microscopical image, of 2′, or at all events of 4′ (which is about the eighth part of the moon's apparent diameter), is certainly quite sufficient for distinct observation. If indications of shape or arrangement should be found in the image, which are too minute for the powers given above, they must be at any rate of minuter dimensions than the values of δ assigned by the first table. Indications of that kind— if such there be—have no true relation to the objects, but are attributes of the image only—mere optical phenomena, dependent upon the limitation of the delineating pencils by the lens-opening.

Apart from all theory and experimental demonstration in support of the principles in question, the practical experience of microscopists has sufficiently established that there *is* a limit to the performance of the Microscope, and one depending on the aperture of the objectives in the manner pointed out above. No kind of microscopical object can possibly afford in any respect more favourable conditions for the recognition of minutest details than those very expressive (and at the same time very simple and regular) structures of the silica skeleton of diatoms. But even with this kind of object not one *trustworthy* observation is on record in favour of the assumption that any given aperture, be it either 0·3 or 1·40, could reach a finer detail than is assigned by the table above, whilst there are many indubitable proofs that these theoretical limits may be as closely reached as can be expected, having regard to the difficulty of a strict determination of the actual circumstances of observation.

The low figures of amplification suggested above, even for the widest attainable apertures—low in face of the views of many microscopists—are an unavoidable inference from the principle under consideration. In support of this inference I may, however, appeal to the evidence of many experienced naturalists who have done valuable work in lines of research dealing with the most

minute and delicate objects, and who agree that all real increase of our knowledge, even in these branches, has been originally obtained, or at least could have been as well obtained, by powers not much exceeding 1000–1200, whatever kind of lenses may be in question.

2. I cannot, however, restrict myself to the suggestion that *excess of power*, in proportion to the aperture in use, is simply of no advantage for the recognition of microscopical objects, but I must go further still, and express the opinion that excessive power is, or at least may be, a positive obstacle to *correct* recognition, because it will unavoidably lead the observer to take mere optical pheno- mena of the images for real attributes of the objects. The following considerations will justify this view.

If we observe a frustule of *Pl. angulatum* with the small aper- ture of about $0·6$, in which case one set of lines only is exhibited at once, we may obtain a well-defined image of these lines under a power of 1000 diameters, or even more, provided a relatively short focal length of the objective and a moderate eye-piece are applied, and the illumination is effected by a very narrow beam of intense light. This power *apparently* displays much more than a lower power of 350 or 400 diameters with the same aperture. We see the striæ as broad ridges or grooves widely separated from one another, and we recognize a distinct proportion between the breadth of these apparent ridges and their interspaces, which is 1 : 1 very approxi- mately; whilst with 300 diameters we only catch just the fact of a striation, and nothing more. In this case now, we know that all details which are given by the 1000 diameters are mere optical illusions, because we are able to control and correct the indica- tions furnished by that power with the low aperture, by the image presented by an equal power, but having an aperture of $1·2$. But if it had happened that a system of wider aperture than $0·6$ had not hitherto been made, microscopists would cer- tainly have believed in the existence of ridges and grooves of equal breadth on the scale of *Pl. angulatum*. In this example it is unquestionable that the image obtained with an aperture of $0·6$ under 300 diameters is *less far* from the truth than the image with the same aperture under 1000 diameters. The *indeterminate* striation is an indication of real structure, inasmuch as there *are* equidistant rows of elements in the diatom, which must appear as striæ as long as the elements themselves remain occult; the exhibition of these rows as determinate ridges and interspaces *with a distinct relation of breadth* is a positive adulteration of the image of the structure.

What holds good for an aperture of $0·6$ must also hold good for every larger aperture *relatively*. I have before me Dr. Wood- ward's magnificent photographs of *Amphipleura pellucida, Pl. angu-*

latum, and other diatoms, taken with the best wide-angled lenses under amplifications of about 3000 and more diameters. Now the *Amphipleura* of these photographs, taken with apertures of 1·2–1·3, is the true equivalent of the *Pl. angulatum* of 1000 diameters with only 0·6 aperture. It shows the same determinate and energetic striation *with equally broad ribs and interspaces*, which are always seen when the closeness of the structural elements is not far from the limit of separation for the aperture in use. Theory and experiment show that these details of the image have no relation to the real composition of the object, that they exhibit nothing more than *typical* pictures of rows of elements of any shape and magnitude whatever, when their closeness approaches the value of δ corresponding to the aperture. It would be contrary to all analogy to expect that in *Amphipleura* alone we should have real bands or ridges, and not, as in other diatoms, distinct elements of double periodic arrangement with different closeness in different directions. This admitted, the enhanced expressiveness and determinateness of the image with the higher power is just the opposite of enhanced recognition, because the eye is caught by features which are entirely foreign to the object. If I wanted to show to any one what the Microscope has *really* revealed of the structure of diatoms, I should request him to inspect the said photographs at a distance of three or four feet, in order to restore the smaller visual angle corresponding to an amplification of about 1000 diameters. What he is able to recognize under these circumstances are the *vestiges* of true structure—indefinite, perhaps, but not falsified; what he sees *more* under greater visual angle is nothing but the display of dissimilarity of object and image arising from the lack of aperture. The 3000 or 4000 diameters could improve the recognition of the *real* structure, only if they were obtained by apertures of 3·0 or 4·0.*

It is by no means otherwise with the very minute objects of entirely different lines of research. If the image of a bacterium or a very delicate flagellum is exhibited under a power of 3000 diameters with more distinctness, as regards shape and magnitude, than is possible with one of 1000, the surplus will always be a surplus of mere optical dissimilarity.

The effects of excess of power in the Microscope may be illustrated by similar facts of astronomical experience. Astronomers

---

* The figures of the tables should not, however, be applied directly to photographic performance, but the powers indicated for each aperture should be *increased* in the proportion of 0·41 : 0·55 (3 : 4 approximately), and the aperture corresponding to a given power *diminished* in the same proportion. Owing to the shorter wave-length of the rays of maximum chemical intensity, the value of δ for every aperture is proportionately smaller in photographic than in ocular observation.

know very well that the most *trustworthy* power of a telescope is not the highest power which the instrument will bear, but that power which has a certain relation to the diameter of the objective. If they use a higher amplification than about 40 per inch of the diameter of the objective (i. e. 120 for a 3-inch, 400 for a 10-inch objective) they begin to detect diameters of stars which have no diameters. A very good 3-inch objective will, indeed, show more under a power of 300 than of 100, apparently ; just the same as with a very good wide-angled Microscope-lens in regard to 3000 and 1000 diameters. In fact, the 300 diameters of the 3-inch will reveal, with somewhat bright fixed stars, very neat and distinct disks which are invisible, or nearly invisible, under a power of 100. But these disks disappear at once, when the amplification of 300 is obtained with an objective of 9 inches diameter.* Astronomers are accustomed to apply much higher powers than 40 per inch for various purposes ; but they do *not* apply them whenever they want to recognize the *true* shape and magnitude of their objects.

It is just the same in the Microscope. The greatest possible approximation of the image to a true projection of the object is not obtained by the highest powers, but by those powers which are just capable of exhibiting to the eye the least dimensions of real structure within the reach of any given aperture.

I invite the particular attention of microscopists to this subject, as it is in my opinion of great practical importance in regard to the proper *use* of the Microscope. For my present purpose I may confine myself to the statement that it does not belong to the rational aim of microscopical optics to enhance the *amplification* of the Microscope beyond those moderate figures which are sufficient for utilizing the attainable apertures ; the rational aim is rather to obtain the best possible accomplishment and the most favourable conditions, for the use of these moderate amplifications.

3. So much as to the proper relation of aperture and amplification at the *upper* end of the scale of microscopical performance, where the question is of the largest attainable apertures and highest useful powers. In regard to the *lower* end of the scale, the suggestions indicated by Tables I. and II. will require some further remarks.

So far as the principle is admitted on which the computation of the tables has been based, we must consider the small apertures assigned for the lower powers of the Microscope as sufficient,

---

* The physical conditions of the phenomena in question are not *the same* in the telescope and in the Microscope, but yet very similar. In both cases the effects do not arise from deep oculars—as is often assumed—but depend only on the relation of the total amplification of the instrument to the aperture.

provided a visual angle of not less than 2′ is required for the smallest detail within the reach of every aperture. An increase would be a matter of necessity only if a given observer should consider a smaller visual angle, say 1′, as sufficient for distinct observation. On the other hand, it is certain that a surplus of aperture is no drawback by itself, but only in regard to certain practical points, which have been spoken of in the first part of this paper. Among these are some which argue in favour of *small* apertures (penetration, working-distance, insensibility of the corrections, &c.), and one which is in favour of *increased* aperture (brightness of the image). The proper function of the theoretical considerations of the foregoing paragraphs cannot therefore be to establish an *absolute* rule, but rather to afford a proper basis for finding a rational balance between the various requirements of the practical use of the Microscope.

Regarding those in which the advantage is always on the side of the *lower* aperture, it will be obvious that all of them become less and less important as lower apertures and lower powers are in question. As has been pointed out in the first part, restrictions of the working distance and inconvenient sensibility of the systems (unsteadiness of the corrections for different thicknesses of the covering glass, &c.) are not met with as long as the aperture does not exceed 0·25 (about 30°) and even with somewhat greater apertures, up to 0·5, they do not occur in any very obnoxious degree. The third element, the penetration of the Microscope, has been more fully discussed on another occasion,[*] where it was shown that with decreasing amplification the *actual* penetration, i. e. the depth which is accessible to the eye with *one* focussing, is more and more the result of the accommodative faculty of the eye and more and more independent therefore of the aperture. With very low powers, not much exceeding 50 diameters, a normal eye has a perceptible amount of depth of vision without any regard to the aperture. The lower the power, therefore, the more liberty is left for increasing the aperture in proportion to the power without any perceptible disadvantage in respect to the various points above mentioned.

There is, as I have said, *one* element in the performance of the Microscope in which a *surplus* of aperture will be a benefit, viz. the illuminating power, or the brightness of the image. It would, however, be a great mistake to expect that this should be without any limits or conditions, as the following considerations will show :—

So far as the illumination of the objects by transmitted light is effected with light of a given intensity, and the illuminating pencils utilize the whole aperture of the objective, the brightness

* See this Journal, i. (1881) p. 689.

of the microscopical image depends solely on the diameter of the pencils at their emergence from the ocular, and is in the direct proportion to the square of that diameter. This diameter (d) is strictly expressed by the simple formula

$$d = 2a \cdot \frac{l}{N} \quad \left(\text{or } d = 2l\frac{a}{N} \right);$$

if N denotes the amplification of the ultimate image for a distance of vision $= l$, and a the numerical aperture of the system. If we have a narrower illuminating pencil, which does not fill the whole opening of the system, the numerical aperture corresponding to the angle of the illuminating pencil must be substituted for a, instead of the full numerical aperture of the system. The diameter of the emergent pencils, and consequently the illuminating power, is entirely independent of the particular composition of the Microscope (objective, ocular, and length of the tube), and is solely determined by the aperture and the total amplification (the accidental losses of light by reflection and absorption being disregarded). By giving values to l and $\dfrac{a}{N}$ we obtain from the above formula the diameter d in millimetres. Under the assumptions made in the computation of the figures of the second column of Table II. (i. e. $\lambda = 0\cdot55\ \mu$ and $v = 2'$) we have a *constant* ratio of $a : N$, viz. :—

$$\frac{a}{N} = \frac{1}{2\,(264\cdot5)};$$

and taking $l = 250$ mm. and substituting those values in the above formula we have

$$d = \frac{250}{264\cdot5} = 0\cdot95 \text{ mm.,}$$

consequently the same diameter d for all powers, and always the same brightness of the image therefore, provided the different apertures are fully utilized by the incident illuminating pencils.

By increasing the values of a assigned for every power N by Table II. we enlarge the diameter of the emergent pencils in the same proportion; we should, for example, have $d = 1\cdot9$ mm. throughout, if the apertures—so far as this is possible—were increased in the ratio of 1 : 2, which would correspond to the assumption of a visual angle $v = 1'$ for the least accessible detail. It is obvious, however, that larger apertures can be of advantage only so long as the value of d does not exceed the diameter of the pupil of the eye under the actual conditions of microscopical observation; for if this should happen, the iris of the observer must stop-off the marginal part of the lens-opening exactly in the same way as if a diaphragm were placed on the objective.

Moreover, in microscopical observation—except under very faint illumination—the iris of a sound eye always contracts to a relatively narrow diameter, generally not more than 2 to 2·5 mm. Whilst, therefore, so far as delineating power alone is concerned, the largest useful aperture (for $v = 2'$ as in Tables I. and II.) is $\dfrac{a}{N} = \dfrac{1}{2\,(264\cdot5)}$ or $a = \dfrac{N}{529}$, the *maximum* aperture for every amplification of the Microscope will be given by the general formula above, if d is taken $= 2\cdot5$. We then obtain, from $a = d\,\dfrac{N}{2\,l}$,

$$a = 2\cdot5 \cdot \frac{N}{500} = \frac{N}{200};$$

and conversely $N = 200 . a$ as the *minimum* power required to enable the eye to admit all rays which emerge from the ocular. An aperture of $0\cdot5$ (60°) will therefore be useless in *every* respect (in regard to light as well as delineating power) as long as it is applied with powers of less than 100 diameters, and the same will be the case with an aperture of $0\cdot25$ (29°) for all powers below 50 diameters. Moreover, *proper* utilization of the rays which are admitted through a given aperture, will require still further restriction. For if the diameter of the pencils at their emergence from the ocular should closely approach the pupils' diameter the least motion of the eye will cause a stopping-off of this or that portion of the aperture. The observer will therefore seldom utilize the full pencil, and will have the awkward sensation of a continual change of the illumination of the image.

All this considered, it must be concluded that the *utmost* amount of aperture which can be really useful under the general circumstances of microscopical work, will be, for every power, about *twice* the figures indicated by the second table. This corresponds to an increase of the emergent pencils to a diameter of nearly 2 mm. (1·9 mm). Every larger proportion between aperture and power must be considered as decidedly irrational, because it is not only *waste* of aperture in every respect, but at the same time a positive disadvantage for convenient and proper observation.

Up to the limit here assigned, I admit the benefit of increased aperture, so far as the *lower* and *lowest* powers are in question, for which the other requirements—as has been shown—do not impose greater restrictions. In my opinion, the benefit of the increase is, however, not so much the gain of light by itself, but rather the advantage, *that narrower illuminating pencils, which do not fill up the whole aperture of the objective, may be applied without inconvenient reduction of light.* The smaller apertures which are sufficient for properly utilizing the delineating power of the objectives would also be quite sufficient in regard to light, provided the inci-

dent beam always utilized the full area of the objective. In point
of fact, a system of $a = 0 \cdot 2$ (23°) applied with a power of 106
diameters will not show any want of light under that condition, even
with dull daylight. The deficiency which, under all circumstances,
is found in the use of high powers (notwithstanding correspondingly
wider apertures) has no other cause but that we are not allowed to
apply illuminating pencils as large as the full aperture of the Micro-
scope. With the exception of some particular cases, the utilization
of wide apertures in observing delicate objects will always require
such *narrower* incident beams of light (generally of no greater angle
than 30–40° in air) as utilize *directly* a small portion of the aperture-
area only; the effect of the wider aperture being to collect those
rays which are dissipated to large angles by the structural elements
of the objects. The actual brightness of the image which is ob-
tained under these circumstances is of course much less than it
would be if an illuminating pencil equal to the full aperture could
be employed. The proper effect of low apertures is, it is true, much
less dependent upon the reduction of the illuminating beams.
Nevertheless, such reduction—by means of diaphragms below the
preparations—is an important benefit in many observations. For
that purpose it is of practical importance that the aperture should
be *greater* than would be required for the brightness of the image
under full illumination. If *twice* the value of a assigned by
Table II. is admitted for the several powers, these powers will still
afford sufficient light, even if incident pencils of half the aperture
only are used for illumination, and three-quarters of the clear
area therefore is left for the utilization of dissipated rays.

4. We have now all necessary data for defining, at any rate in
outline, a *rational standard* for the ratio between aperture and
power in regard to the *entire* Microscope, i. e. the amplification of
the *ultimate* image (without considering at present the participation
of objective and ocular).

(1.) So far as those apertures are in question which cannot at the
present time be overstepped, the aim must be to obtain the most
perfect performance for those powers which are just sufficient for
the full utilization of the delineating capacities of these apertures.
The figures of N assigned by Table I. may thus indicate the par-
ticular aims for the various kinds of lenses—dry, water-immersion,
homogeneous-immersion—in regard to those values of a which must
be considered as the practical limits for these various systems
(i. e. about $0 \cdot 95$ for the dry, $1 \cdot 25$ for the water-immersion, and
$1 \cdot 45$ for the homogeneous-immersion systems respectively). For
the full development of every system a reasonable latitude for
further increase of power, beyond the limits of strictly useful powers,
must, however, be left.

(2.) So far as the medium powers are in question, which are *below* the limits of useful powers for the maximum apertures, but still *above* those amounts which could be obtained by very moderate apertures, a somewhat strict *economy of aperture* is indicated by important considerations in regard to the general demands of scientific work (penetration, working distance, &c.), because the disadvantage of superabundant aperture will be always greater than the possible benefit.   For the medium powers in use, the figures of Table I. will therefore give the approximate limits of latitude which may be deemed reconcilable with a rational construction of the Microscope for *scientific work*.

(3.) Concerning the lower and lowest powers, a gradually increasing latitude is left for the application of wider apertures than would be theoretically necessary in regard to the delineating capacity required for these powers.   A surplus of aperture increasing up to about 100 per cent. for the lowest amplifications, will be in favour of the *illuminating power* of the Microscope; a considerably greater excess will at all events be mere waste.*

* The concluding part of the paper—ii. *Division of the Entire Power of the Microscope between Objective and Ocular*—will be printed in the next number of the Journal.

XII.—*Description of a Simple Plan of Imbedding Tissues, for Microtome Cutting, in Semi-pulped Unglazed Printing Paper.* By B. Wills Richardson, F.R.C.S.I., Vice-President University of Dublin Biological Association.

I am emboldened to publish the following description of a method for imbedding tissues of suitable consistence for microtome cutting, as it may have some claim to originality, imbedding in semi-pulped paper being unnoticed in any of the standard works on microscopic manipulation which I have had opportunities of searching. Be this as it may, very thin and perfect sections can be cut with rapidity in semi-pulped paper, from either animal or vegetable structures of sufficient firmness to remain uninjured while being sent home in the microtome well. I think, however, that imbedding in semi-pulped paper will probably be found to have a more extended range of usefulness for vegetable section-cutting rather than for cutting animal structures.

Although tissues submitted to the process should have a certain amount of firmness, as I have just observed, they should not, on the other hand, be so dense as to offer much resistance to the knife, very unresisting structures being unsuitable for this mode of imbedding.

The diameter of the tissue to be cut should, when feasible, be one-quarter of an inch less than the diameter of the microtome well. Indeed, a microscopist's laboratory ought to be provided with microtomes having wells of different diameters that both time and tissues may be economized.

Stems of plants previous to cutting may, with advantage, be stored in methylated spirit for a few weeks; and animal structures, in whatever fluid has been found most appropriate for their preservation and, if necessary, for their hardening.

I shall now give the steps of this easy method :—

Cut strips, eight to nine inches long, from white unglazed printing-paper, the width of each strip to be a little more than the length of the structure to be imbedded. Transfer the latter from the preservative fluid to filtered water, in which leave it for about half an hour, then dip one of the strips of paper in the water for a few seconds, remove it and drain the water rapidly off its surfaces. Take the structure to be cut out of the water, apply one end of the wetted paper to a portion of its circumference, and roll the paper around the structure as closely as the paper will allow of without tearing. If necessary, apply more wetted paper until both the paper and inclosure form a plug that should require a little

pressure for sending it home in the microtome well. If too much paper has been applied, tear off the superfluous portion until the desired calibre is attained.

The paper when wetted will, of course, stretch, but a little practice soon teaches the operator to roll it with only the tightness necessary for allowing the imbedded tissue to be cut without break.

In careful hands dozens of perfect sections may be cut in half an hour from very delicate stems $\frac{1}{8}$ of an inch in diameter, or from the delicate aereal-roots of certain orchids. But I should mention that a pine-apple stem $\frac{6}{8}$ of an inch in diameter has afforded me most perfect sections when imbedded in the semi-pulped paper.

Up to the present time (April 1882) the only animal structures I have had leisure to imbed and cut in semi-pulped paper were decalcified human teeth, and a diseased external iliac artery removed from the body of a child, one of whose lower extremities I removed by amputation at the hip in March 1879.

From the "dentinal cartilage" I obtained several thin and instructive specimens.

The artery did not bear the knife to my satisfaction, having partially "rotted" from a too prolonged immersion in Müller's fluid.

Further experience of pulped paper as an imbedding medium may lead to an extended use of the paper for animal-tissue section-cutting. But I prefer to conclude here, at all events, with a stronger recommendation in favour of pulped paper for supporting vegetable tissues in the well of the microtome under the restrictions I have mentioned. It is almost superfluous to add that each section should be floated off the knife in water, and that a little of the latter should be carried by the blade to the semi-pulped paper in the well, to maintain it at the requisite degree of saturation for efficient cutting.

The advantages which I consider the method to possess are :— (1) Facility in application ; (2) almost unlimited application in vegetable section-cutting under the restrictions above mentioned ; (3) rapidity in cutting ; (4) the tissues are equally supported ; (5) cleanliness ; (6) heat not being used, the subsequent staining of sections is more equal.

XIII.—*Note on the Rev. G. L. Mills' Paper on Diatoms in Peruvian Guano.* By F. KITTON, Hon. F.R.M.S.

(Read 14th June, 1882.)

IN the last volume of the Journal, p. 865, Mr. Mills has figured and described a new species of *Auliscus, A. constellatus.* After reading his description and carefully examining his excellent figures, I was satisfied that his species was identical with that described by Herr Janisch in his ' Zur Charakteristik des Guanos,' Breslau, 1861–62, as *A. Stockhardtii ;* it is also figured in Schmidt's ' Atlas der Diatomaceen-Kunde,' Tafel xii. figs. 11–13. Schmidt remarks that fig. 13 = "*A. racemosus* Ralfs (Greville Monograph of the Genus *Auliscus*, T.M.S. vol. xi. 1863, p. 46, pl. iii. fig. 18) doch Janisch's Benennung ist älter." This is undoubtedly correct, and Ralfs' specific name must be deleted.

I communicated the result of my examination to Mr. Mills, who at once admitted the correctness of my views, and, moreover, had the kindness not only to send me the specimens of his supposed new species, but also most generously gave me his specimen of *Aulacodiscus Kittoni* with fourteen processes. On examining this I congratulated myself on possessing a probably unique but certainly a very beautiful state of this species. Examining it again a few days afterwards, I found, in consequence of the balsam being still soft, that a valve of *Aulacodiscus Comberi* had partially slipped over it. I resolved upon remounting it, and succeeded in placing it on another slide ; during the process I caught a glimpse of the *f. v.*, which induced me to examine it again very carefully with a binocular and $\frac{1}{4}$ objective, when to my disappointment I found that our supposed fourteen processed *A. Kittoni* was composed of the two inner valves (each with seven processes) of a double frustule ; these were in close proximity—in fact, the two convex surfaces touched each other, the elevations on one surface fitting into the concavities of the other, thus accounting for the fact, noticed by Mr. Lewis, that the processes appeared " all in the same plane, and all equally and distinctly defined." The number of processes in *Aulacodiscus* and *Eupodiscus* are now generally admitted to be of no specific value, but it is more constant in some species than in others, e. g. *A. formosus.* I have never seen more than four processes, and on some valves I have observed as few as three, but in every case they were abnormal forms. In all other species the number is more or less variable. In a pure and recent gathering of *A. Kittoni* I have seen no valve with more than six processes, four being the usual number, but abnormal forms are by no means rare. I have seen a six-rayed valve with four of the rays at right angles to each other,

the remaining two being close to the opposite rays (processes). The most remarkable abnormally is a valve without process or αὔλαξ, but with the former faintly indicated near the margin.

It is only right to add that these remarks on Mr. Mills' paper have been written at his request, as he does not wish an error to remain uncorrected.

SUMMARY

ZOOLOGY AND BOTANY

(principally Invertebrata and Cryptogamia),

MICROSCOPY, &c.,

INCLUDING ORIGINAL COMMUNICATIONS FROM FELLOWS AND OTHERS.*

ZOOLOGY.

A. GENERAL, including Embryology and Histology of the Vertebrata.

Division of Embryonic Cells in the Vertebrata.†—L. F. Henné-guy, in studying cell-division as exhibited in the ovum of osseous fishes, finds that that of the trout, on the third or fourth day after fecundation, if treated with a mixture of acetic and picric acids, is the best adapted for this investigation; the cells are then seen to be formed of a finely granular protoplasm, and contain a nucleus of some size.

The nucleus of a cell in a state of repose contains a plexus, formed of small irregular granulations, which are especially well stained by carmine. The nucleolus is only a little larger than the other granulations. Soon there appears around a clear space, of which the centre is occupied by the nucleus, very fine clear lines, which are set along the rays of the cell, and which together form an aster; this aster elongates and becomes elliptical, as does also the nucleus; the aster then divides, and the two halves each form a fresh aster; at this moment the membrane of the nucleus disappears, and the rays of the aster penetrate into the interior. The plexus now breaks up into a number of small rod-shaped bodies; these become set at the extremities of the rays, and form the so-called equatorial plate. Gradually the rods diminish in size but increase in number, and fuse to form a pectinate figure. The body of the cell then begins to be constricted in its middle, the rays of the aster disappear, and the connective filaments alone remain to unite the two nuclei, until at last the cells become completely separate. The new nucleus, due to the fusion of the rods, is highly refractive, and is intensely coloured by reagents;

* The Society are not to be considered responsible for the views of the authors of the papers referred to, nor for the manner in which those views may be expressed, the main object of this part of the Journal being to present a summary of the papers *as actually published*, so as to provide the Fellows with a guide to the additions made from time to time to the Library. Objections and corrections should therefore, for the most part, be addressed to the authors. (The Society are not intended to be denoted by the editorial " we.")

† Rev. Internat. Sci. Biol., ix. (1882) pp. 363-5.

as it increases in size, there appear the limiting membrane and the internal plexus.

At a later stage of development, when there has been multiplication of the cells, these become smaller and smaller, and the asters gradually become quite indistinct. In the earliest stages of segmentation the process of division is more difficult to follow, owing to the large size and very granular contents of the cells; on the first and second day the cells become so uniformly tinted that the nuclei are with difficulty made out. As the cells diminish in size the action of the colouring matter becomes more and more confined to the nucleus, and the author is of opinion that the chromatin of Flemming is at first uniformly distributed through the cell, and that it gradually separates to form a constituent of the nucleus.

Genesis of the Egg in Triton.[*]—Mr. T. Iwakawa records the result of observations on the genesis of the egg of the common Triton (*T. pyrrhogaster* Boje), in which he describes the manner of depositing the egg (the female turning upside down so as to place it *under* the leaf or stem), the structure of the ovary, origin of the ovum and Waldeyer's "epithelial islands" (the author's view being that the ovum does have an epithelial origin), the formation of yolk-spherules, the vitelline membrane, the germinal vesicle, and the "yolk-nucleus."

Formation of Fibrine.[†] — In 1879 Dr. Norris described the alleged discovery of a third corpuscular element in blood in the form of colourless disks, which he considered to be an earlier stage of the red corpuscles. [‡] This was criticised by Mrs. Ernest Hart in the following year,[§] her view being that they were red corpuscles that had undergone post-mortem changes prior to taking part in the formation of fibrine.

Continuing her investigations and repeating the experiment of "isolation"[||] a great number of times, she began to observe that the appearances changed according to the length of time which elapsed between the spreading of the layer of blood between the two glass surfaces and the moment when the cover-glass was raised, and thus discovered that a whole series of phenomena could be traced, leading from the pale or colourless corpuscle up to the complete formation of networks or bands of fibrine. In developing this method of working it was found that the staining reagents recommended by Dr. Norris were not sufficiently powerful to bring out all the details that could be observed on the glass surfaces, and after many trials a highly concentrated solution of nitrate of rosanilin in absolute alcohol was found to be the best staining reagent. The method adopted was to detach the cover-glass from the slide after the corpuscles had been fixed by osmic acid vapour, and to examine both the surfaces of the cover-glass and the slide, to see which presented the most perfect preparations.

---

[*] Quart. Journ. Micr. Sci., xxii. (1882) pp. 260–77.
[†] Ibid., pp. 255–9 (1 pl.).
[‡] See this Journal, iii. (1881) pp. 229–32.   [§] Loc. cit.
[||] See description, loc. cit.

Having made a selection, a drop of the concentrated solution of nitrate of rosanilin was deposited on the glass and allowed to remain for a few moments, and then washed off with a fine jet of distilled water. The red, pale and colourless corpuscles, with their ramifications and the most delicate fibrils of fibrine, then become visible under a high power. The preparations may be mounted dry, and will keep for a great length of time. If the process be performed as rapidly as the dexterity gained by an oft-repeated experiment will allow, it will be observed that the circular appearance of the corpuscles is perfectly preserved, and that every shade of colour may be found, from the normal red corpuscles down to the colourless Norris corpuscle, which only takes the faintest tint of pink. If, however, the glass surfaces be allowed to remain in contact for a moment, the colourless corpuscles are found to have lost their globular form, and to have become pyriform or elongated. On leaving the glass surfaces still longer in contact, these pale corpuscles are observed to undergo a remarkable change. They send out long processes or tails, which bifurcate and divaricate in every direction. On allowing a still longer interval to elapse, so that it is more than probable that coagulation would occur in a film of blood lying between two glass surfaces, and on separating these surfaces, perfect specimens of fibrine may be obtained after staining. On now searching the field, the pale corpuscles, which could formerly almost always be discovered, are nowhere to be found, and the conclusion is forced upon one that the branching corpuscles have developed or broken down in fibrinous threads. Small granules are, however, found from which threads of fibrine appear to spring. These granules are described in Ranvier's 'Traité Technique d'Histologie' as the centres of fibrine formation. They appear to the author to be all that is left of the pale corpuscles, whose intermediate transformations have not before been recognized, but may perhaps be identified with the appearances and changes described. Amongst other figures, one is given showing the departure of the fibrils of fibrine from the pale corpuscles.

New Blood-corpuscle.[*]— According to G. Bizzozero, if the circulating blood in the small vessels of the mesentery of chloralized rabbits or guinea-pigs is observed under a high power, there will be seen, besides the ordinary red and white cells, a third form of corpuscle which is colourless, round or oval, and from one-half to one-third the size of the red corpuscle. He considers that they have hitherto escaped the notice of observers (1) owing to their translucency and want of colour; (2) because they are less numerous than the red, and less visible than the white corpuscles; (3) owing to the great difficulty of observing the circulating blood in the small vessels of the warm-blooded animals. They can be seen also in freshly drawn blood, for the most part aggregated around the white corpuscles, or immediately under the cover-glass, to which they adhere. They soon become granular, and give rise to what is called the granule-masses. Through appropriate reagents their form can be preserved.

* Arch. Ital. de Biol., i. (1882) pp. 1–4; cf. 'The Microscope,' ii. (1882) pp. 59–60.

A solution of salt coloured with methyl-violet has this property. The best method of examining them in the human subject is to place a drop of the above coloured solution over the puncture and mix the drop of blood thoroughly with it.

Owing to their typical forms, it is very unlikely that they are derived from the red corpuscles. The colourless corpuscles contain no ingredients from which they could be derived. After bleeding, and in many diseased conditions, they are increased in numbers. They play an important part in the formation of thrombi and the coagulation of the blood, which has been attributed by Mantegazza and Schmidt to the white corpuscles, because the latter are few in number in the circulating blood, and their destruction was never observed by Bizzozero, provided the blood was mixed with a saline solution. Again, the time at which coagulation sets in corresponds very closely to the time that these new corpuscles undergo degeneration. The fluids which retard or prevent coagulation—as solutions of carbonate of soda and sulphate of magnesia—have the same action in preventing the granular degeneration of these corpuscles. An indifferent solution of salt does not preserve them, but one to which the methyl-violet has been added does.

From this evidence it appears (to the editor of the ' Cincinnati Medical News ') highly probable that the formation of fibrine takes place under the direct influence of these corpuscles. To them Bizzozero gives the name of " Blutplattchen."

Life and Death in the Animal Organism.*—After completing an important investigation on the " Earliest developmental operations in the ovum, on cell-division, and on conjugation in the Infusoria," O. Bütschli, early in 1876, wrote an essay headed " Thoughts on Life and Death," but he left it unpublished, considering, on the one hand, that his ideas on the differences between Protozoa and Metazoa in respect of the phenomena of death were too recently acquired to be made known, especially in print, and that, on the other hand, the speculations which he had associated with these ideas were too immature to be made permanent. His fundamental views, however, namely those relating to the non-existence of individual death in the Protozoa, have now been published.

" If we glance over the phenomena of the origin and destruction of beings in the great series of animal organisms, we are astonished by a significant contrast in the importance of individuality in the higher, i. e. the many-celled, as compared with the lower, i. e. the unicellular, forms, the Infusoria or Rhizopoda. Whilst in the first the individual, in almost all cases, asserts an existence definite and distinct even from its progeny, in the unicellular forms, on the contrary, which reproduce by fission, we are met with the fact (which does not usually receive much attention) that at the time of reproduction the individual, as such, ceases to exist, and divides its individuality equally between the individualities of its two offspring, which now come into existence. This remarkable phenomenon

* Zool. Anzeig., v. (1882) pp. 64-7. Cf. Naturforscher, xv. (1882) pp. 125-6.

appears in the most striking light when we endeavour to realize in these lower forms the idea of death, such as we have been led to consider it from observations of the higher animals. Death in the higher organisms is not the total extinction of life, but only of the individual existence; but the reproduction of a unicellular organism constitutes at the same time its death. On the other hand, however, by the idea of death in the higher organisms is implied an actual separation of organized substance from the activity of life, in other words, an annihilation of previous life. This element is entirely wanting in the individual death of the Protozoa, that is, in its reproduction; it goes on living all the same, though in the persons of its progeny.

If we study the development of certain Protozoa,—the Infusoria,— we come upon the highly remarkable fact that death does not occur in them, in the sense of annihilation of organic material and from causes inherent in the organism itself. Although these organisms, in the course of their life, are threatened by death under a thousand forms, yet this takes place by "accidents," and thus the few individuals which reproduce the species are to be considered of equal importance with the multitude which perish, for the few reproduce by fission only, and are thus immortal; while the many which die could have reproduced their species just as well as the others, if they had had the same favourable opportunity; not one of them necessarily carries in it the seeds of death.

Whoever wishes to construct a hypothetical representation of the fact that in the higher animals the individual is limited in its duration to a certain time, will find a tolerably simple plan open to him. If we hold it to be allowable to consider the peculiar vital manifestations of the cell, the fundamental element of every form of organization, as caused by the presence of a substance which acts in a certain sense like a ferment,—necessary to the production of those chemical changes in the cell which result in vital manifestations, but gradually, though perhaps slowly, used up,—then the limited duration of the life of one of the higher animals may be intelligibly represented by assuming that the ovum out of which this organism once originated acquired a certain amount of this ferment-like substance, which is gradually exhausted during life, and with the final exhaustion of which the end of the individual existence coincides.

It is otherwise with the Protozoa, which reproduce by simple division. These organisms have also this characteristic vital ferment, but they also enjoy the peculiarity of being able to renew it; hence it is not exhausted in them, and they are not overcome by death in consequence of its being used up.

But the power of forming this vital ferment is shared by the higher organisms as well, but here it is localized, being confined to the generative organs. In the other cells composing the body the material we have been speaking of is gradually and increasingly used up in the course of their active existence; but in the generative regions, whose cells maintain their primitive character longest, fresh vital ferment is accumulated for their posterity. Certain appearances occur which, perhaps, justify us in forming an approximate idea as

to the place in the cell which this material with its property of evoking life occupies. Among these the chief are the phenomena of conjugation of Infusoria, taken in connection with facts recently acquired in the study of the process of fertilization in the Metazoa. The gradually diminishing vital energies of the Infusoria are strengthened afresh by conjugation, and this comes about by a partial or total renewal of the nucleus from the so-called nucleoli or primary nuclei. A total or partial renewal of the nucleus of the ovum is also seen in fertilization, and it is most probably effected by the spermatic nucleus.

(This passage was written in 1876, when the first and imperfect account of the process of fertilization had just been put forth; but it would be easy to alter it so as to bring it into accordance with our present knowledge, without interfering with the part played by the nucleus.)

Thus the failing vital powers of the Infusoria are raised up again by the renewal of the nucleus, and a similar result occurs in the process of fertilization; is it not, therefore, a justifiable conclusion that the vital ferment which has been spoken of, actually resides in the nucleus of the cell, whenever this is present. It is not the whole nucleus which is to be interpreted in this way, but only a small part of its bulk. Thus in the case of the Infusoria, it must be assumed that the freshly produced life-ferment is collected more especially in the so-called nucleoli, but in higher organisms in the reproductive cells, chiefly in the nucleus of the male reproductive elements."

N. Cholodkowsky, in discussing * the doctrine of Bütschli, points out certain difficulties in the way of our accepting this view. Some forms, e. g. *Hydra*, have an asexual as well as a sexual method of reproduction; now, if all the cells of such an animal have the power of producing new individuals they must all be immortal; yet, as a matter of fact, we know that many die down. It seems to Cholodkowsky that the cause of the death of the Metazoa is to be sought for in the multicellularity of their organism. A cell has in itself and for itself a potential immortality; but as soon as differentiated cells are united into an individual there commences amongst them a struggle for existence, which, *eo ipso*, leads to destruction. The hypothesis of Bütschli recalls the Darwinian doctrine of Pangenesis; just as Darwin supposed a general distribution of reproductive cells throughout the organism, which only later became concentrated in the generative cells, so does Bütschli deal with his vital ferment, and the doctrine of the latter is therefore only a more physiological way of expressing that of Pangenesis.

Pelagic and Deep-Sea Fauna.† — T. Fuchs enumerates the distinguishing characteristics of the pelagic and the deep faunas respectively, and makes some inductions as to the reasons for these peculiarities. Pelagic animals are those which are wholly independent of the shore and the sea-bottom at all stages of their existence.

* Zool. Anzeig., v. (1882) pp. 264–5.
† Verh. k. k. Geol. Reichsanstalt, 1882, pp. 49 and 55. Cf. Naturforscher, xv. (1882) pp. 199–202.

Most of them are transparent and colourless, and thus invisible in water; where colour occurs, it is usually violet or blue, resembling that of the water; the fishes are chiefly steel-blue above, silvery-white below. Most forms are naked; the shell, if present, is comparatively delicate. A large number are viviparous, even when their nearest allies are oviparous.

A great number of pelagic animals are phosphorescent. Nearly all are admirable swimmers. Some have their surface-area largely developed, e. g. the tests of Radiolaria, of *Globigerina*, *Hastigerina*, &c., probably in order to hinder sinking. As to the manner of life, they are almost without exception social, they mostly have a very wide distribution, and are found alike in the Atlantic, Indian, and Pacific Oceans; the genera are almost all identical in these seas, although polar seas are distinguished from warmer waters by possessing few forms besides Crustacea, Pteropoda, Cephalopoda, and Cetacea. In connection with their usually delicate structure stands the fact that it is only in the calmest weather that they live on the surface; storms may drive them to a depth of more than 50 fathoms. Further, far the majority only come to the surface in the night, a point to be considered in connection with the prevalence among them of phosphorescence; the time of appearance of the phosphorescent fish is more often connected with the night than with any other time. Pelagic animals seldom occur except over deep water, and at great distances from coasts, hence their scarcity in the German Ocean, their poverty in littoral and their abundance in deep-sea deposits.

The deep-sea fauna is distinguished by the appearance or predominance of certain individual species, genera, and families, and exhibits little variation in the different parts of the world. It commences at a depth of about 50 fathoms in all seas, but it is only in the tropics that anything like a sharp line of demarcation is found between it and the littoral fauna. Examining these points to ascertain the reason for a bathymetric limit of this particular nature, Fuchs finds that it cannot be due to temperature, although this diminishes as the depth increases, for in the Red Sea the warm zone extends much below 50 fathoms, while in polar waters even the surface has a low temperature, and currents operate besides so as to introduce great irregularity into the bathymetric relations of temperature; however, the fact that 43 to 50 fathoms has been ascertained to be the limit to the penetration of light into the sea appears to him good evidence that the presence or absence of light is the determining agency sought for, and that the littoral fauna is simply the fauna of the light, the deep-sea fauna that of darkness. This view is supported by the more superficial distribution of deep-sea forms in some places in which the limit of light lies at an inferior depth, and the deeper range of littoral forms in fresh waters, where the light has greater penetration. The large eyes or blindness of so many, the pale or monochromatic colour of most, and the phosphorescence of a large number of the animals which compose this fauna is evidently connected with the absence of light. The resemblance of the pelagic to this fauna is intelligible if it is remembered that it too is most in its element in

the darkness. Resemblances between cave faunas and that of the deep-sea point also to a common cause in the absence of light. The range of some littoral forms into great depths may perhaps be found to be due to their being nocturnal in habits.

The cavities which occur under coral reefs off Brazil may perhaps shelter a fauna of deep-sea character, owing to the absence of light there; hence it would be not unlikely that geologists might find similar aggregations of deep-sea animals in formations otherwise composed of littoral reefs. Otherwise the relations of deep and littoral faunas were probably much the same in geological times as now, owing to the similarity of their relations to the light, and the differences here indicated can, in point of fact, be traced throughout all formations.

B. INVERTEBRATA.
Mollusca.

Anatomy and Classification of the Cephalopoda.* — Dr. J. Brock commences with a study of *Rossia*, the knowledge of the anatomy of which is confined to the short description given by Prof. Owen. As a result of the new investigations we find that *Rossia* is, as has been supposed, most closely allied to *Sepiola*; the relations of these two forms to the Myopsida, and especially *Sepia* and *Loligo*, are by no means so clear. The author's earlier investigations led him to the belief that the affinities of the different forms might be well shown by this diagram :—

Sepia.

—Rossia————Sepiola.

—Loligo.

—Ommastrephes.
The presence, however, in *Rossia*, of fused lower salivary glands points to its affinities with the Œgopsida, and this would lead us to form a table in which *Loligo* should stand above *Rossia*, or nearer *Sepia*. As to the relations of *Sepiola* to the form last named, it might be supposed that *Sepiola* had branched off from the Decapod stem independently, but the Octopod characteristics of *Sepiola*, as seen in its musculature, are to be found also in *Rossia*, and it requires evidence of a kind very different from that which we have at present to lead us to believe that these very similar arrangements could have been independently developed by the two forms. The Octopod type of the musculature of *Rossia* is still further developed in *Sepiola*, and that in a way which justifies us in regarding the latter as a direct descendant of the former. A useful table is given in which are enumerated twelve characters and the respective resemblances and differences of *Ommastrephes*, *Rossia*, and *Sepiola*.

If the view that *Rossia* and *Sepiola* form a line of development which branched off from the Decapod stem shortly before *Loligo* be

* Zeitschr. f. wiss. Zool., xxxvi. (1882) pp. 543–610 (4 pls.).

correct, we find in it what may be spoken of as parallel-developments
with the Myopsida and Octopoda ; we find, that is, in this side
branch a series of differentiations which have, for the different organs,
a most remarkable resemblance in those two series.   Just as from
Loligo to *Sepia*, so from *Rossia* to *Sepiola* we find the upper salivary
glands lost, the accessory nidamental glands fused, the efferent duct
of the ink-bag sharply marked off, and the lateral teeth disappearing
from the middle plate of the radula.   From *Ommastrephes* to *Sepia*,
just as from *Rossia* to *Sepiola*, the fused lower salivary glands are
separated, and there appears a characteristic arrangement of the ova
in the duct.   Likewise, there is in *Sepia* and *Rossia* a shortening of
the inner pallial nerves, which finds its termination in the absence
of these in *Sepiola* on the one hand, and the Octopoda on the other.
A very instructive diagrammatic table is given by the author to
demonstrate the points on which he insists.

If we enter into still wider generalizations, the facts observed by
the author lead us to see that in the Dibranchiate Cephalopoda, long
before the separation of the phylum into the Octopoda and Decapoda,
there must have been a tendency, under suitable, though still un-
known, conditions, for the cartilaginous articulations with the mantle
and funnel to yield to firmer membranous or muscular cephalic
joints ; thrice, or twice at least, did this tendency exert its influence.
In connection with this there must also have been a tendency to the
reduction and final loss of the upper salivary glands, the separation
of the lower ones, and the fusion of the accessory nidamental
glands.

Dr. Brock then passes to a second study of the generative organs
of the Cephalopoda ; in dealing with the female organs of the
Œgopsida it is pointed out that the nidamental glands may be absent,
as in *Enoploteuthis*, or that they may be present, with (*a*) the oviduct
lying ventrally to the gills, as in *Ommastrephes sagittatus*, or (*β*) the
oviduct may open with a buccal invagination of the integument, lying
dorsally to the gills, as in *Om. todarus*, *Onychoteuthis*, or *Thysano-
teuthis*.

A study of the generative organs of the Philonexidæ shows us
that they may be thus arranged :—
1. Subfam. Hectocotyliferæ.   ♂ with a free *Hectocotylus*.
       a. Philonexidæ S. Str.   Hectocotylus without dermal frills.
              No water-vascular system—*Argonauta*, *Philonexis*.
       b. Tremoctopodidæ.   Hectocotylus with dermal frills.   A
              water-vascular system—*Tremoctopus*.
2. Subfam. Parasiridæ.   Free hectocotylus not known, but pro-
       bably present.   ♀ with very long oviducts, viviparous.
       Parasira.

In dealing with the gland of the oviduct, it is pointed out that
the following series may be detected in the Octopoda :—
1. Gland consisting of a series of cæca arranged radially around
the oviduct; no increase in the extent of the secreting surfaces
—*Argonauta.*
2. The secreting surfaces of the gland well developed, and a

circlet of strongly developed receptacula seminis.interpolated between the gland and the oviduct—*Tremoctopus violaceus*.

3. The receptacula seminis not so well developed; a fresh gland developed between them and the primitive gland—*Parasira catenulata*.

4. No receptacula seminis; the walls of the primitive and of the secondary gland highly developed, and in the latter so far advanced as to lead to a fusion of the glandular sacs—*Octopus, Eledone*.

Various as are the forms of the oviducal gland in the Octopoda it is important to notice how uniform they are in the Decapoda.

The author then enters upon a consideration of the so-called water-canals and the viscero-pericardiac cavity; he finds that the genital capsule of the Octopoda is the (reduced) direct homologue of the viscero-pericardiac cavity of the Decapoda; and that the water-canals of the Octopoda correspond to the anterior, while the genital capsule corresponds to the hinder portion of the viscero-pericardiac cavity of the Decapoda. And he concludes with accounts of *Tremoctopus ocellatus* n. sp., *Octopus pictus* n. sp., *Loligo bleekeri*, and *Cranchia reinhardti*.

Ink-Sac of Cephalopoda.[*]—P. Girod publishes a full and detailed account of his study of this organ.[†] By a careful dissection, first of the peripheral trabeculæ, and then of the apex of the pyramid formed by the formative zone, we come upon the cellular mass which forms the central portion of the trabeculæ. When a portion of the tissue of this part is teased out, elongated cylindrical cells may be detected which, in their general character, are not unlike the cylindrical cells of many mucous membranes; the large nucleus which occupies the narrower end of the cell becomes very apparent on the addition of colouring reagents. The cell itself, on high magnification, is found to be divisible into two portions: the larger of these is coloured yellow by picrocarmine, and seems to be formed of a hyaline liquid, which is limited on the nuclear side by a faint, slightly concave, and granular line; the second and narrower portion contains a granular protoplasm. The constitution of the cell suggested to the author that it belonged to the calyciform series, but the absence of any orifice did not seem to him to justify that view. Near these cells others may be seen which contain black granulations in their upper portion; these are not cylindrical, but are divided by constrictions into three portions; the uppermost colouring matter is bounded externally by the cell-membrane, and is also distinctly separated from the nucleus. On the whole, there is a very close connection between these and the cells of the first set, the hyaline mass in the latter being now filled with pigmented granulations, and the part which contains the nucleus having been elongated. Other cells present other characters; in some there is a much larger aggregation of pigment, whence two lateral prolongations descend, one on either side of the nucleus: here, too, slight pigmented granu-

---

[*] Arch. Zool. Expér. et Gén., x. (1882) pp. 1–100 (5 pls.).
[†] See this Journal, i. (1881) pp. 227, 586, and 876.

lations are to be seen within the substance of the nucleus. In others the black granulations are so richly developed as to completely obscure the nuclear mass, although that body is still present. Finally the cells commence to undergo degeneration, their membrane breaks, and the pigment escapes; the nucleus, however, still persists, and it is in consequence of this that we find free nucleated masses in the midst of the pigmented granulations. The author discusses in order the histological characters of the meshwork, the wall of the pouch, its internal, median, and external tunics.

Turning to the development of the ink-sac, we find that on the fourth day of the second period (that of the development of the organs) the anal depression comes in contact with a process of the mesoderm, and then divides into two portions, the superior of which is the ink-sac, and the inferior the rectum. The former rudiment has at first a transverse direction, and extends from the anal orifice to the internal yolk-sac, and is clothed by a single layer of epithelial (ecto-dermic) cells. This is what will form the vesicle. The cells at the cæcal extremity soon begin to multiply and form a thickening which is the rudiment of the gland. The glandular mass developes rapidly by making its way into the midst of the mesoderm; the cells of that layer now begin to form peripheral layers around the gland, till they nearly completely surround it, and the mass becomes divided into two lobes, between which there is an extension of the mesoderm. Changes in the cells themselves now appear, and give rise to the formation of a thick granular liquid. As soon as the glandular cavities are developed the investing cells take on the characters which belong to the formative zone of the adult, and a peripheral and a formative zone are thus developed. Further changes bring about a connection between the gland and the reservoir; the latter then begins to increase rapidly in length, and at the same time to dilate. Still further changes, in the mesoderm, give rise to the different investing layers, and there is some alteration in position. Looking more generally at the matter, we find that the ink-sac is formed by an epidermal invagination, which, during development, is differentiated into two parts, the gland and the vesicle (reservoir); this invagination is contained in a kind of mesodermic sac, which forms the tunics that envelope the epithelium; the innermost of these consists of an epithelial and of a connective layer, the median of the silvery and of a muscular layer, and the outer of connective tissue. When we compare this with the integument, we cannot but be struck with the remarkable similarity between them; there, too, we find an epithelium, the cells of which are arranged in a single row, and limited externally by a thick cuticle; the connective layer contains the chromatophores, and beneath this there are a silvery layer, muscular fibres, and a layer of connective tissue. The absence of chromatophores in the region of the sac may be explained by a study of the intermediate stages presented by different parts of the body.

The researches of Lacaze-Duthiers on the purple-glands of certain Gastropoda have led the author to make a study of these structures, from which it results that their anal gland is homologous with the

ink-sac of the Cephalopoda, and this view is strengthened by a consideration of the nervous supply. In the Gastropoda the glands in question receive filaments from the " asymmetrical centre," in the Cephalopoda the nerves come from the visceral or inferior ganglion which corresponds exactly with that centre.

If we compare the ink-sac of the Octopoda with that of the Decapoda we find that there is in the former an arrest of development, the reservoir not being elongated or widened out; in consequence of this close relations still obtain between it and the anal orifice, and the gland and reservoir are closely applied to one another. It is to be borne in mind that the tetrabranchiate Cephalopoda are without the organ, and that it is only some of the Gastropoda which possess one, and that that one is always much simpler in character.

The physiology of the question is also dealt with, and it is pointed out that three stages may be distinguished in the excretion of the ink: (1) there is a continuous passage of ink from the gland into the vesicle—due to a *vis a tergo*, and to the compression exercised by the limiting membrane of the gland and the nodosity of the vesicle; (2) an intermittent passage of the ink from the vesicle into the sac, due to the contraction of the vesicle; (3) spasmodic expulsion of the ink by the funnel, due to the spasm of expiration. The nerve-branches from the visceral nerves were found to be motor filaments, presiding over the contraction of the wall of the vesicle.

Sense of Colour in Cephalopoda.[*]—How highly developed the sense of colour is in insects has been shown by Sir John Lubbock in his interesting observations on bees, wasps, and ants. For the development of the same sense in animals of a different type C. Keller brings forward evidence taken from the cuttle-fishes, which manifest in a high degree the power of adapting the colour of their skin to that of the environment. Keller was able to observe this adaptation of colour in *Eledone*. In the Naples Aquarium a specimen of this Octopod was under the necessity of flying from a powerful lobster; during its flight it appeared pale red; but subsequently, resting on a tuft of yellow rock covered with brown spots, it imitated the yellow ground-colour with its brown spots so closely that it became almost invisible to the observer. In this case the conditions were decidedly very favourable for the occurrence, for yellow and dark-brown colour-cells occur in *Eledone* in large numbers. It should be added that the eye of the cuttle-fish shows an unusually high development.

'Foot' of certain Terrestrial Gastropoda.[†]—Mr. J. Wood-Mason describes the structure of the part of the foot called by German writers on malacology the *Fuss-saum* which, as no technical name for it appears to exist in the English language, he proposes to call the *peripodium*, in allusion to its relation of position to the locomotor ventral surface or foot of the molluscs possessing it, but which he thinks may be homologous with the lateral folds (epipodia)

---

[*] Vierteljahresschr. Naturf. Gesell. Zurich, xxvi. (1881) p. 100. Cf. Naturforscher, xv. (1882) p. 40.

[†] Proc. Asiatic Soc. Bengal, 1882, pp. 60-2.

of many marine molluscs (*Haliotis*, e. g.). Very frequently the peripodium is provided at its posterior extremity with a capacious pit, the capacity of which may be increased by the prolongation upwards of its anterior margin in the form of a horn, which not being specially sensitive is not a tentacle, often it is without this terminal pit; it is invariably richly ciliated throughout from the mouth on one side round to the mouth again on the other side dorsally; equally invariably is it limited off from the side of the body (and frequently also from the muscular foot) by a peripheral groove, which deepens anteriorly. Its office is to assist in lubricating the foot, the pit when present receiving the effete lubricating fluid and throwing it off in gelatinous lumps.

The foot-gland, as is well known, pours out its abundantly and constantly flowing secretion through an aperture which is situated below and a little behind the mouth into a hollow whence it naturally falls into the deep anterior end of the dorsal peripheral groove, whence again it is carried by the cilia with which the surface of the peripodium is beset (being distributed to the foot as it goes) to the terminal pit. In those forms in which this pit does not exist, the secretion that has served for lubrication is merely left behind by the crawling mollusc.

As Pulmonata possessing a ciliated peripodium with and without a terminal pit are to be found in every quarter of the globe, and as it is in the highest degree improbable that so highly specialized a structure, subserving such an important purpose in the animal economy as this evidently does, has arisen independently many times in many different forms in many widely separated areas of the earth's surface, the author considers that it has a higher taxonomic value than has hitherto been assigned to it, and he feels strongly inclined to distinguish those forms that possess it and those that do not (or have lost it) from one another by calling them Craspedophora and Lipocraspeda respectively.

Mucin of Helix pomatia.[*]—According to H. A. Landwehr, when the mucin of *Helix pomatia* is treated with 1 per cent. sulphuric acid, it yields grape-sugar, whereas mucin from other sources yields only a reducing substance. The grape-sugar cannot be derived from glycogen, since the iodine reaction fails entirely in the freshly expressed secretion, and in the mucin prepared from it. The author however, succeeded in obtaining a carbohydrate, for which he proposes the name "achrooglycogen." In order to prepare it, he directs that the mucin obtained from the snails shall be treated with 5 to 10 per cent. caustic potash, and the proteïds separated by Brücke's solution (potassiomercuric iodide), the solution filtered, and the filtrate precipitated by alcohol. The material thus obtained, after being washed with absolute alcohol and dried, is an amorphous, white, tasteless powder, readily soluble in water. The solution is strongly opalescent, gives no iodine reaction, and does not reduce an alkaline copper

solution. By boiling with acids, or by digestion with saliva or diastase, the substance is converted into dextrin and grape-sugar.

Rhodope veranii.*—Professor L. Graff gives an account of this form, which was regarded by Schultze as a Turbellarian, and named *Sidonia elegans;* he has been able to demonstrate that it is not a worm, but the Nudibranch long ago described by Kölliker under the name of *Rhodope veranii.* The largest examples are about 4 mm. long, with a breadth of ⅓ mm.

The integument consists of a single stratum of cylindrical epithelial cells, and is pretty closely invested by long cilia; this integument is pigmented, and a figure of the curious arrangement of the colour, under what the author regards as its typical form, is given. Calcareous spicules, of some size, are to be found under two different forms, embedded in the parenchyma of the body. The mouth lies at the anterior end, but is sometimes held dorsally; the cavity into which it leads is provided with closely appressed small papillæ, but there is no indication of anything like a radula. After some account of the other parts of the digestive system, of the nervous system, and of the generative apparatus, Dr. Graff states that, like Kölliker, he searched in vain for any indication of a heart or blood-vessels. The numerous small oval corpuscles which fill the cœlom were suspended in a colourless fluid, which appears to be set in motion by the movements of the body, or the contractions of the enteron. The author was, however, enabled to discover a water-vascular system similar to that of the Platyhelminthes. Strong magnification revealed actively moving flagella, scattered through the body, and similar to those which are found in the excretory system of various Vermes. Each flagellum is continued in a vesicular enlargement, and by its widened base completely closes the ciliated funnel, the free end of the flagellum being directed towards the efferent canal. No exact information can be given as to the branchings of the excretory system, or as to the character of its orifices.

The absence of gills, buccal mass, and radula, as well as of a vascular system, proclaims *Rhodope* to be the very lowest of all known Nudibranchs; at the same time it is distinguished from the allied Turbellaria by its anus, by the structure of its generative organs, its central ganglia, and its sensory apparatus. *Rhodope* must not, however, be supposed to have been derived from the present specialized Dendrocœla, but from a group of Rhabdocœlida, to which, in his forthcoming Monograph of the Turbellaria, the author intends to apply the term Alloiocœla; this group will contain *Vorticeros* and others, and will be distinguished from the Acœla and the true Rhabdocœla by characters which will, we think, be better understood when that subject comes before us.

Molluscoida.

Test-Cells in Ascidian Ova.†—These cells, so characteristic of the ova of Tunicates, obtained their name from the belief that they

* Morph. Jahrbuch, viii. (1882) pp. 73–83 (1 pl.).
† Zool. Anzeig., v. (1882) pp. 356–7.

eventually formed the test enveloping the Ascidian. This view was shown to be erroneous, and Professor J. P. McMurrich now enunciates a new theory as to their function.*

The latest theories on the subject of parthenogenesis and of the nature of polar-globules are based on the assumption of the bisexual nature of the ovum, on account of which it is possible, and there is even a tendency, for a yolk to divide spontaneously. In most cases this is disadvantageous, and the formation of " test-cells " is a means of guarding against the misfortune. On the exposure of the ova to sea-water or other abnormal condition a contraction of the yolk is brought about, and thereby a tension upon the nucleus, which, under the strain to which it is subjected, would divide, and so start the process of segmentation, were that strain not removed from it by the extrusion of the test-cells, whereby it is preserved intact until the proper stimulus in the shape of a spermatozoon excites it to a healthy and normal division.

This theory the author would also suggest as an explanation of the *Excretkörper* described by Hertwig and Oellacher as appearing in the ova of Amphibia and fish respectively, and also of the fatty globules described by the late Sir Wyville Thomson as occurring in the eggs of *Comatula*, to which structures test-cells bear no little resemblance.

Embryology of the Bryozoa.†—J. Barrois finds that the larva of a Bryozoon consists essentially of five principal parts; an aboral surface, the peripheral part of the oral surface with the corona which is only the edge of it, the incubating pouch with the central part of the oral surface which is destined to form the intra-tentacular space, the intestine, and lastly, the rudiment of the polypite which already exists in the larva, where it forms a special organ, and takes more or less a part in the formation of the polypite.

In the Entoprocta these parts have most nearly the arrangement which is found in the adult; the aboral surface forms the integument of the larva, and the oral is retractile and can be withdrawn into the vestibule; the only change necessary to convert the larva into the adult is a rotation of the incubatory pouch and the intestine so as to bring them into relation with the rudiment of the polypite. In the Chilostomata there is developed, by the aboral growth of the corona, a pallial cavity;—as the oral surface has here lost its retractile power, there must be a change in the position of the mantle before the larva can pass into the adult condition; here, therefore, there is a more marked metamorphosis. In the Ctenostomata the pallial cavity is enormous, and the cells of the corona are of very large size; in the Cyclostomata there is no corona, but the oral surface continues to grow towards the aboral pole; and here, therefore, we have, in its most marked condition, the process which has become more and more

* In a previous paper he showed that the test-cells were produced by a contraction of the yolk of the ovum, consequent on the action of various stimuli being formed, more or less distinctly according as the stimulus was capable of causing a greater or less contraction of the egg-contents.

† Journ. Anat. et Physiol. (Robin) xviii. (1882) pp. 124-61 (1 pl.).

marked the further we are removed from the Entoprocta; in consequence of this the oral surface, which was at first entirely enclosed in the interior of a cavity (the vestibule) and covered over by the aboral surface, has gradually passed more and more to the exterior so as to form by itself the external integument and to drive the aboral surface into the interior of a cavity (the pallial cavity). In the most differentiated types of the Chilostomata and Ctenostomata we have seen that the aboral surface has been driven into the interior; notwithstanding this, the uppermost portion of this surface which forms the organ called the " calotte " has always been seen to be projecting. In the Cyclostomata, however, the pallial cavity is always closed and covered over. Adding to these the Lophopoda, we may make the following table:

Entoprocta	Predominance of the aboral surface. Vestibule at its maximum. Intestine well developed.
Chilostomata and Ctenostomata (sac reduced)	Predominance of the corona. A pallial cavity. The intestine reduced to a mass of globules.
Cyclostomata and Lophopoda (no sac).	Predominance of the oral surface. Pallial cavity at its maximum. Intestine disappeared.

The author points out that from the point of view of larval forms only we seem to find an essential character in the antagonism of the two great cavities at the poles, and, when we carry this further, in the greater or less development of the mantle. It is according to the extension of this last that we find one or other of the two surfaces of the larva best developed; when there is a median extension of the mantle we find, moreover, that the intestine has partly disappeared; while when it is at its maximum condition of extension there is no intestine at all. When we come to look at the matter in a more general way we see that this development of the mantle is not a matter of so great importance, inasmuch as every form of larva, no matter to what type it belongs, can always be referred to a common type, in which there is no mantle, in which the oral surface is always within the vestibule, and the aboral forms an integument. The history of the mantle is, then, only a history of a series of adaptive modifications.

Dealing with the mechanism of the metamorphosis, M. Barrois finds that if we try to construct a general type of adult Bryozoon we have to recognize (1) a foot corresponding to the oral pole, (2) the frontal surface, corresponding to that which answers to the oral, and (3) a tergal or anal surface. In the Entoprocta these can be easily made out, but in the Ectoprocta it is not always so distinct; in the forms where the zoœcium is elongated we seem to have the primitive disposition, in the flattened ones the tergal surface is increased in extent; palingenesis is to be seen in the Ectoprocta, cœnogenesis in the Entoprocta.

As the author regards the Bryozoa as belonging to the Vermes he notes that, with the exception of the Rotifera, the Bryozoa are the only Vermes in which a telostomiate condition is constantly manifested, either in the larval or in the adult condition; in other words, the division of the body is on the primitive or gastrula

type, in which we see an oral and an aboral pole. A free-swimming Entoproctous larva is then formed on the same type as a Rotifer. Granting this, we must suppose that the Bryozoon is the result of a simple change of life; we know that these larvæ often creep about on their oral surface. If this habit were to become permanent we should have in the change of habits a sufficient cause for the metamorphosis; the ciliary current carrying food to the mouth would, on passing it, abut against the anal extremity of the vestibule, and would gradually drive this back towards the superior extremity of the larva; there would thus be produced the rotation, in which the digestive tube would be implicated. We may assume the earlier existence of a group of Probryozoa, free-swimming creatures, of a general Rotiferform, only represented to-day by the larvæ of some of the Entoprocta; these on taking to creeping would have their form altered by a current of water.

New Adriatic Bryozoa.*—Dr. Piesser discovered in some material sent him from Rovigno in the Adriatic a Bryozoon, which he found difficult to determine on account of its having some of the characters of *Gemellaria* and some of *Notamia*, but he calls it *Gemellaria*, and considers that the definition of the genus must be widened to receive it.

It consists of rows of double cells back to back, and the aperture occupies most of the front. A zoœcium does not spring immediately from the zoœcium below as in *Gemellaria loricata*, but grows in the manner of *Notamia bursaria;* further, at the commencement of each branch instead of a pair of zoœcia, there is only one, out of which a pair grow. There are radicle fibres which start from the back of a pair of cells and grow out independently, instead of uniting together and growing in a bundle down the dorsal surface of the colony.

The most perplexing point to Dr. Piesser was the occurrence of avicularia at the top of the zoœcia, sometimes sessile and very minute, at others they are much larger and pedunculate. He thinks that these characters show that it is a connecting link between *Gemellaria* and *Notamia*, and if his interpretation is correct, about which opinions may perhaps vary, we may look upon this as another instance showing that the presence or absence of avicularia cannot often be relied upon for generic division. It may interest Dr. Piesser to know that although this curious species has not previously been described, yet it lives in the Bay of Naples, and has also been found from a locality outside the Mediterranean.

Arthropoda.

a. Insecta.

Sensations of Sight conveyed by the Facet-eye.†—The experiments of Grenacher, Dor, and Exner, as to where the rays received by the compound eye of Insects ought to be and are concentrated, led to the most contradictory results, until Grenacher finally established the true view. Several points, however, as to the quality of the

* Neunter Jahresber. Westfälisch. Provinzial. Vereins für Wiss. u. Kunst, 1881.
† Abh. Senckenberg. Naturf. Ges., xii. (1880) pp. 35–123 (3 pls.).

function of vision still required investigation. The close parallel with the Vertebrate eye which was attempted to be drawn, is quite fallacious. Clearness of sight was said by Joh. Müller to coincide with long sight, and to be best exhibited in those eyes which have the greatest circumference—the greatest number of very small facets, large crystalline cones and dark pigment-mass; the nearer the object to the eye, he said, the clearer the view obtained of it.

Dr. J. Notthaft believes the size of the facets and the length of the radius of the curve of the eye to be the only factors in its structure which have an important bearing on this point. With regard to the effect produced by the presence of a number of receptive and refractive units—the units of the compound eye—he believes that the edges of the units and fields of sight are in contact; when the curve of the eye is perfectly spherical the fields are approximately polyhedric, like the facets, but when the curve is eccentric, distortion appears as magnification increases. The smallest angle of sight is constituted by the angular distances between the directions in which two neighbouring retinal elements look, or even between two such ocular elements regarded as wholes. A few examples may be given of the actual condition of things in some specific eyes :—

	Difference of direction between two terminal elements.	No. of Facets.	Smallest Angle of Vision.	Breadth of Facets.	Radius of Curve of Eye.	Distance at which the Sight-field of a unit = 1 cm.
				mm.	mm.	
Apis mellifica ..	104°	54	1° 56′ (or 0° 51′)*	·024	$\left\{\begin{array}{c}1·62;\\0·75\end{array}\right\}$	67 cm.
Formica rufa (worker)	51°	35	1° 27′			
Sphinx convolvuli	67°	39	1° 43′			
Acherontia atropos	20°	13	1° 32′ (or 0° 42′)*	·037	3·0	81 cm.

* Determined by calculation from the radius of the eye-sphere as compared with the breadth of a facet.

In spite of its large minimum angle of vision, the insect eye affords, under certain circumstances, as great an amount of distinctness of vision as the human eye, or even greater; for there is no minimum limit to the distance of vision, and objects near the eye are seen more clearly than anywhere else; the distinctness of vision diminishes as the square of the distance from the eye: these relations for the following insects are:—

	Distance in mm. at which the Clearness		Amount of Clearness with a Distance of	
	= 1.	= 0·1.	0.	60 cm.
Apis mellifica	1·35	7·77	3·36	0·000024
Sphinx nerii	0·81	8·51	1·67	0·000035

The indistinctness produced by distance has the effect of reducing the image of (e. g.) an *Ailanthus* leaf to an outline in which the different lobes are almost entirely merged together, and almost all the detail lost (cf. Figs. 88 and 89).

Exner's view of the impression produced on the insect eye of the degree of rapidity of movement in any objects, viz. that it is inti-

FIG. 88.
Leaf of *Ailanthus glandulosa*, showing part taken by the different portions of the compound eye in viewing it.

FIG. 89.
Effect produced on the retina by the leaf thus viewed.

mately connected with the movement of the insect itself, must lead to absurd conclusions. Joh. Müller's view, that insects see objects only by means of the accurate perception of their illumination, is the most important point in the theory of mosaic sight (that of

compound eyes), and contains the key to its principle. Only those rays of light can affect the eye which fall on it in the radial direction, i. e. in the direction of the long axes of the crystalline cones. Each retinula (retina of a single unit) receives a cylindrical bundle of light-rays from every visible object; exactly the same amount of an object is taken in, at whatever distance it is viewed, so the effect of motion is not produced by an increase in or reduction of the amount which is seen of a moving body.

The action of direct sunlight on insects is evidently, from their sensitiveness to it, of great importance to them. Seeing that the angle which the rays proceeding from the orb of the sun make on reaching the earth is on the average 32′, the smallest angle of vision for a unit of any insect's eye being probably more than 10′ (39′ is the lowest known to the author, viz. in an *Æschna*), the single image of the sun would be spread, at the most, over three unit-eyes, and, at the least, over one; while the minute unit of the human eye, having an angular distance of 10″ only, can take in $\frac{1}{192}$ of the sun's disk, and thus the disk occupies in the retina a surface 192 units in diameter, and covering about 27,000 rods. The amount of light which can be received directly by the facetted eye from the sun is far less than that received by the human eye, in fact only from $\frac{1}{9000}$ to $\frac{1}{27000}$ of the amount received in the latter case. The bearing of this striking fact on the habits of the insect is difficult to see, but it may be asserted that the insect's eye is thus well provided against the effects of a too intense light, while its sensibility to minute grades of illumination from terrestrial objects remains incontestably one of its most important properties. For by far the greater amount of the impinging light is absorbed by the epidermic structures, and owing to the spherical curvature of the eye, the rays which reach it coincide in direction with the optical axes of but a few of the units, and so but a small portion of the receptive nervous region is affected by them; thus only the $\frac{27}{10000000}$ part of the sun's disk is perceived by a single eye. This view is supported by Grenacher's opinion that it is the median (i. e. direct and unrefracted) rays of the pencil which strike a facet, which are the most important. The perception of an object in all its dimensions and of its relation to surrounding bodies cannot be *learned,* as it is to some extent in our own case, during the short life of the insect. Some idea of the character of the insect's vision may be gained from the observed fact that the natural impulse of the insect is to court the darkness (e. g. the lower sides of leaves, the shade of grass, &c.), in order to avoid observation; their well-known delight in brilliant illumination forming merely an episode in their life of caution. Probably they are to some extent subject to optical delusion; thus when the sun suddenly goes behind the clouds, the surrounding objects, before so brilliantly illuminated, would appear to be at a greater distance, owing to their loss of light. To ascertain the relations of objects with regard to the surrounding space is the most important function of this organ in these animals, and especially the relation of distance from the eye itself; these ends are attained by the comparatively large angular distance which

the closely apposed elements present. The actual distinctness of the features of the object is less important here than with the human eye.

The reason for the existence of two forms of eye, simple and compound, in perfect insects, is that of separating the impressions of space and distance from those of distinct sight of the object (the latter end being attained by the stemmata or simple eyes). Four, on the whole strongly distinct, kinds of vision are differentiated in the animal kingdom :—

1. General sensation of the *amount of light* evolved in the environment and of the relative position of its source ; analogous to our sensation of warmth, and exhibited only in small organisms with transparent outer coverings, and devoid of special portions of the body adapted for the function. 2. Sensitiveness to colour and shades of colour ; general orientation as to environment, power of recognizing known objects—the "eye-spots" of Vermes, &c. 3. Information as to relative positions of surrounding objects affording guidance of movements, with slight amount of guidance as to characters of object—compound eye of *Arthropoda*. 4. The most clear and faithful perception of the objects, the images reversed by a lens which strongly refracts light. The contents of a *plane* are the subject of this kind of vision, which does not convey to the brain the distance or mutual relations of objects ; the plane may be either single, at a constant distance from the eye, or there may be several at distances which vary within certain limits, as when *accommodation* comes into play. In this case the third dimension, viz. depth or distance of objects, is obtained by movements made by the eye-bearing individual, relatively to the objects viewed, materially aided by the power of accommodation, when this is present ; in its absence, as in the case of the *stemmata* of Arthropoda, this impression must be very feeble, since the moving animal obtains nothing but a disconnected series of images of the objects as they come one by one within the range of its organs.

The phylogeny of the compound eye is deducible from the fact of the acquired character of the movements of Arthropoda ; as the faculty of motion became better developed, the organs of sight became modified, *pari passu*, into that form which successfully met the requirements of this mode of motion, in the manner above explained ; the highest degree of development being naturally reached in the Insecta. All winged insects are thus provided, while but few of the wingless forms, such as larvæ, &c., have this form of eye.

The explanation of the peculiar character of the vision enjoyed by the compound eye lies in the lenticular curvature of the corneal facets, which do not act as Joh. Müller supposes, by magnifying the entering rays, but by admitting only those which are not likely to prove injurious ; this appears to be shown by a comparison of the Insect with the Crustacean eye. The latter is remarkable (judging by the results obtained by Grenacher from *Mysis*) for its large angle of vision—3° 16′ in the instance taken—and is probably fitted to convey impressions from a distance not exceeding a metre. Taking into

consideration the density and other light-absorbing properties of the medium in which the insects live, the amount of light received from an object must vary approximately as the cube of the distance of the source of light, hence the wide opening of the eye, admitting as much light as possible. The same effect as the perspective which is obtained in air is here produced by the indistinctness of objects, owing to the opacity of the medium, in proportion to their distance from the eye.

The structural causes for these differences are :—(1) the flatness or slight curvature of the Crustacean cornea, which does not hinder the entrance of any light which falls radially upon it, and (2) the strong convexity of the facets in insects, which causes refraction of the rays to a focus in front of the retina, and consequently a diminution of the light which meets them ; thus most of the hurtful rays —those whose direction is not exactly at right angles to the surface of the cornea—having entered the eye at its side, are again thrown to the side and absorbed by the walls and the pigment of the narrow tube, whose diameter at the apex only allows of the entrance of a small central pencil. With regard to the fate of strongly divergent rays, the refractive properties of the cornea would appear calculated to increase their brightness ; but this is the case only with objects at short distances, and has the advantage of giving distinct and recognizable images of objects within this range.

Nervous System of the Strepsiptera.*—The nervous system of the Strepsiptera has not been subject to any special researches. C. Th. von Siebold † only states that these insects (*Xenos vesparum*) have one thoracic ganglion ; but he does not say anything about the number of cephalic and abdominal ganglia. E. Brandt's researches have been limited to four females and one male of *Stylops melittæ*, and one female *Xenos vesparum*, preserved in spirit, the results of which are as follows :—

1. The cephalic division of the nervous system consists of the *ganglion supra-œsophageum* only, the *ganglion infra-œsophageum* being absent.

2. The thoracic division consists of a large ganglion containing five pairs of nuclei ; it is divided into two parts, an anterior and smaller one, corresponding to the *ganglion infra-œsophageum* and to the first thoracic ganglion of other insects, and a posterior and larger part, which corresponds to the other thoracic ganglia and to some abdominal ganglia. The interior division supplies nerves to the organs of the mouth (like the *ganglion infra-œsophageum*) and to the first pair of legs. The posterior and larger division of this ganglion supplies nerves to the second pair of wings, to the thorax, and to different segments of the abdomen.

3. The abdominal division of the nervous system consists of one abdominal ganglion, situated in the last third of the body. It is

* Abstract by the author of a memoir in Russian, St. Petersburg, 1878. Ann. and Mag. Nat. Hist., ix. (1882) pp. 456–7.
† Lehrb. d. vergl. Anat., i. (1848) p. 582.

oval, and is connected with the thoracic ganglion by means of a long thin cord. From this ganglion spring three pairs of nerves, of which the first and second pairs branch out in the fifth and sixth segments of the abdomen, while the last pair branch out in the last segment of the abdomen and in the rectum.

This nervous system is as curious as that of some Coleoptera (*Rhizotrogus solstitialis, Serica brunnea*) and some Hemiptera (*Hydrometra lacustris*), as it has no *ganglion infra-œsophageum.*

Insects which injure Books.—Professor A. Liversidge, of Sydney, sends us some specimens of *Lepisma saccharina,* and points out that " in Blades' ' Enemies of Books,' 3rd ed. (1881) pp. 61–3, he refers to the description of a book-worm in Hooke's ' Micrographia ' (1665), and rather makes fun of the figure and description there given— ' certainly R. Hooke, Fellow of the Royal Society, drew somewhat upon his imagination here, having apparently evolved both engraving and description from his inner consciousness.'

People living in New South Wales and other of the warmer parts of Australia can, however, bear testimony to the accuracy of Hooke's statements and drawing. The insect figured in the ' Micrographia ' abounds here amongst books and papers, and is wonderfully destructive to them. It does not do so much harm to books as it does to loose papers, maps, labels, &c., as it cannot well get in between the closely pressed leaves of a book, and it is on this account that the loose edges of piles of MS., bundles of letters, &c., suffer so much more than the central portions; writing paper, too, probably contains much more attractive matter in the way of size, &c.

With this I enclose some scraps of paper showing the ravages of the insect (*Lepisma*), and also some of the ' silver fish ' themselves, by which name they are commonly known here and also in India, whence I understand the name ' silver fish ' originated.

The destruction of labels is a very serious one, as the identity of a specimen may very soon be lost. The labels enclosed have only been written about fifteen months, and some hundreds have thus been rendered totally useless. In future it will be necessary to saturate the labels with a poison, such as corrosive sublimate.

At times I have thought that, perhaps, the ' silver fish ' instead of doing harm may be doing good—for wherever they are found we are likely to find pseudo-scorpions (*chelifer*), and it *may* be that the former prey upon the latter; though I think not."

Formation of Galls.*—M. W. Beyerinck finds that " galligenesis " affects a portion of the vegetal tissue, which becomes altered in character, and may then be known as *galliplastema ;* the galligenetic influence is due to the larvæ and not to the hymenopterous parent. The phenomenon of formation of the galls is absolutely independent of the lesions which the deposition of the eggs causes in the living tissues of the plant. Direct contact between the animal and the plant is not necessary for the production of the galliplastema ; there may be a layer of dead cells, or even the covering of the egg

* Rev. Internat. Sci. Biol., ix. (1882) pp. 373–4.

between them, and this intermediate space may be greater than the diameter of the larva. In the cases in which the animal that produced the gall had originally only one point of contact with the galliplastema, the further inclusion of the larva is due to an annular investment of the plastema, which increases in extent and becomes folded over it. A temporary contact on the part of the larva does not produce a gall. The larvæ are fed by the development in the gall of a tissue the cells of which have thin walls and contents rich in oil and albumen. In their anatomical structure many of the galls have characters which appear to be completely foreign to the organization of the plants that nourish them.

γ. Arachnida.

Anatomy of Phalangida.*—Dr. R. Rössler finds that the *digestive* system consists of three portions, of which the spacious midgut is provided with a large number of cæca; the sucking action is produced by a layer of strong transversely-striated circular muscles, which is only continued on to the more anterior portion of the succeeding œsophagus; the lumen of this latter region is almost completely filled up by six longitudinal folds, consisting of a transparent cuticle with a subjacent layer; the cells of the salivary glands may be seen, in section, to form one layer and two smaller complexes below the œsophagus; the secretion has an acid reaction. All the thirty cæca are without a muscular investment, and consist only of a thin fat-layer, a tunica propria, and an epithelium; the Malpighian vessels are represented by two tubes, forming a loop, which are placed near the median ventricle, and open not into the intestinal tract, but into two sacs on the ventral surface of the animal.

The *genital* organs of the two sexes are referable to a common plan, consisting as they do of an unpaired germinal gland, semicircular in form, lying freely in the body-cavity, and only surrounded by a rich supply of tracheæ; there is connected with this gland a paired efferent apparatus, which however becomes united into an unpaired piece, and finally opens to the exterior in the median ventral line, between the cephalothorax and the abdomen. Connected with the terminal portion is a copulatory organ, into the anterior portion of which there open a pair of accessory gland-organs; the penis is rod-shaped, the ovipositor is cylindrical, and the vagina has a seminal pouch on either side. The testis is a simple tubular organ about 4 mm. long and 0·4 mm. wide; the spermatozoa are large, biconvex, rounded cells, with a lens-shaped nucleus; the vasa efferentia commence as two fine canals, and soon form a close coil; the cells of the lumen become commingled with the products of the testis; the propulsion-organ has a thick muscular layer, the fibres of which are transversely striated, and there is a thick chitinous layer secreted by the epithelium; the lumen of the ductus ejaculatorius is narrow; chitin is also to be found in the penis. The ovary is horseshoe-shaped, invested by transverse and longitudinal muscular fibres, and when mature is beset with a

* Zeitschr. f. wiss. Zool., xxxvi. (1882) pp. 671–702 (2 pls.).

large number of follicles of various ages.   These, which may be looked upon as evaginations of the tunica propria, all contain an egg, more or less developed, but the ova are always of small size until they make their way into the uterus, which then attain their full size and development.   In the immature female the uterus is only apparent as a slight outpushing of the oviduct, but at the period of maturity it becomes turgescent, swells out, and occupies a large portion of the body-cavity ; it is provided with a powerful layer of circular muscular fibres, and its inner surface is lined with cells, similar in character to those of the vas deferens.   The terminal portion of the vagina is surrounded by a system of chitinous rings ; the ovipositor, like the penis, is surrounded by two sheaths, which are essentially of the same structure in all the species.

The two glands at the lateral margins of the cephalothorax have been regarded by Loman as stink-glands ; the author finds that in *Opilio albescens* there is an aromatic odour, which he ascribes to these organs.

Scent-glands of the Scorpion-spiders (Thelyphonus).*—The remarkable Arachnidan genus *Thelyphonus* is confined in its distribution to South America and Southern Asia and their islands.   Of its internal anatomy nothing but the nervous system is known.   The French zoologist Lucas states that the *Thelyphoni* are called *Vinaigriers* by the inhabitants of Martinique, on account of the strong vinegary odour which they emit when touched or handled.   Stoliczka, who examined living specimens of one of the Indian species, states that a peculiar but *inodorous* fluid issues from two internal pyloric (!) appendages.   These Arachnids, according to Lucas, live in damp places under stones on the ground.   Stoliczka and Mr. Peal found them beneath the bark of decayed trees in groups.

Mr. J. Wood-Mason, who has undertaken an investigation of their anatomy, was only able to obtain specimens for dissection during the heaviest rain, when all vegetation and the ground is saturated with water, and the animals come forth from their holes in the rocks.   He found that death quickly followed their removal from their humid haunts, air saturated with moisture being apparently necessary for the due performance of their respiratory functions.   All the specimens he met with emitted, when touched, a most powerful and lasting odour, exactly like that of a highly concentrated essence of pears, which when deeply inspired had all the characteristic smell and pungency of strong acetic acid.   This odour did not emanate from the general surface of the body, but proceeded from a pellucid fluid which exudes from the neighbourhood of the anus and is secreted by special glands.   These are paired and tubular organs of huge size, extending from the nineteenth somite of the body (on which they open by two minute valvular apertures placed at the sides of the anus) to the front end of the thirteenth in the male, but to the middle of the eleventh in the female (whose glands are consequently the larger), and being, with the exception of the voluminous liver, the most conspicuous of the viscera.   They are two subpellucid bags, shaped somewhat like

* Proc. Asiatic Soc. Bengal, 1882, pp. 59–60.

an Indian club, striped longitudinally with white, and filled to distension with a thin clear fluid. They are not quite equal, nor are they placed symmetrically in the body-cavity, but the one or the other lies between the nervous chain and the ventral body-wall in the middle line between the two rows of vertical muscles, and the other between the row of muscles and the lateral wall of the side of the body to which it properly belongs. They apparently consist of a strong and structureless basement membrane, invested externally by a layer of delicate striped muscular fibres arranged circularly, and of an inner membrane; the walls of the short (1 mm. long) ducts are transversely thickened so as to resemble the tracheæ of insects; the granular tissue is arranged between the two membranes in longitudinal plated stripes, so as to permit of the expansion of the lumen of the tubular organ in a receptacle or bladder for the storing up for use of the secreted fluid, to which apparent arrangement of the granular substance the striped appearance of the organs is due.

The secretion doubtless serves to protect the animal from attack, and it is interesting to find that the female in this, as in so many other animals which are similarly protected by their offensive odour, is (as being for obvious reasons the more important sex) more perfectly protected than the male by having, not indeed, so far as could be detected, a stronger and ranker, and therefore more disagreeable scent, as in many insects, but larger scent-secreting glands. Another point of interest brought out by this investigation is that the two glands exhibit a tendency to coalesce and form a single unpaired median organ, the two being always unequal and occasionally partially united and the one in the middle line invariably the larger.

These structures seem to belong rather to the category of excretory organs than to be highly developed skin-glands; and they are probably homologous with the silk-glands of other Arachnida and of Insects, with the green-gland of the Crayfish, and with the segmental organs of Worms and *Peripatus*.

δ. Crustacea.

Classification of the Brain of Crustacea.[*]—Dr. A. S. Packard gives the following provisional grouping of the brain of Crustacea, which he considers to be justified by known facts, although excepting the brains of Decapoda and *Limulus*, no special histological work has been accomplished. The terms archi-cerebrum and syn-cerebrum have been proposed by Professor Lankester, the first to designate the simple worm-like brain of *Apus*, and the second the composite brain of the Decapoda, &c.

Syn-cerebrum
- Decapoda.
- Tetradecapoda.
- Phyllocarida.
- Cladocera.
- Entomostraca.

Archi-cerebrum
- Phyllopoda.
- Merostomata (*Limulus*).
- Cirripedia?

[*] Amer. Natural., xvi. (1882) pp. 588-9.

The syn-cerebrum of the Tetradecapoda, Amphipoda, and Isopoda, judging by Leydig's figures and his own observations on that of *Idotea* and *Lerolis*, is built on a different plan from that of the Decapoda. The syn-cerebrum of the Phyllocarida is somewhat like that of the Cladocera and Copepoda (Calanidæ); being essentially different from that of the majority of the Malacostracous Crustacea. The Copepodous brain is an unstable, variable organ, but on the whole belongs to a different category from the syn-cerebrum of other Neocarida.

We have then, probably two types of archi-cerebra, and three types of syn-cerebra among existing Crustacea.

Unpaired Eye of Crustacea.*—In most Crustacea, besides the two compound eyes (fused together in the Cladocera), there exists an unpaired median eye. It exists alone in most of the Copepoda, and in all naupliiform larvæ. Wherever the two kinds coexist in the adult but not in the newly hatched larva, the unpaired eye is the first formed, and must therefore be regarded as the primitive eye of the Crustacea. By thin sections of *Cyclops* and *Diaptomus*, Mr. M. M. Hartog has ascertained that this organ is of a much more complicated composition than had been supposed. The pigmented mass is, so to speak, structureless; the colouring-granules in it are placed at the surface contiguous to the "crystalline spheres." Each sphere is composed of radiating elements, the inner ends of which are applied against the pigmented mass, while the peripheral segments contain a nucleus. The eye is situated upon the terminal process of the brain, from which the optic nerves originate, one for each sphere; the nerve, instead of penetrating into the pigmented mass, *skirts the outer surface of the crystalline sphere, and penetrates it directly* not far from its hinder margin. The author has also found in the Phyllopoda a perfect analogy of structure with that just described in the Copepoda, and therefore concludes that the unpaired eye in all the Crustacea that possess it, is composed of three simple eyes, placed anterior to the brain, *with reversed optical bacilli, receiving conductive fibres of the optic nerve upon their outer margin,* and brought so close together that their pigmented or choroid layers are combined in a single mass.

A nearly identical structure may be detected in the Chætognatha, which have the triple eye of the Crustacea; but, instead of being median and unpaired, it is repeated on the two sides of the head; certain Planarians, *Dendrocœlum lacteum* for example, have two paired eyes, which, according to Carrière, have the structure adopted by the author for one of the simple eyes united in the median eye of the Crustacea.

It is probable that the eye of the Chætognatha and Crustacea is to be referred back to the type of the Planarians, but that the two former groups have no direct relationship between them.

Blood of the Crustacea.†—G. Pouchet is reported to find that the differences seen in the blood of these animals is not, as Wharton

* Comptes Rendus, xciv. (1882) pp. 1430-2.
† Journ. Anat. et Physiol. (Robin) xviii. (1882) pp. 202-4.

Jones thought, due to differences in the time of year. Their blood is remarkable for the large quantity of sea-salt which it contains, a drop from a *Maia* laid on a glass slide and dried giving a large number of crystals. Coagulation takes place very rapidly. Notwithstanding the great variation in form of the leucocytes, it is possible to recognize a common type; a large number have the form of young blood-corpuscles of oviparous vertebrates; as they grow older they present a number of granulations, and, as their nucleus is then often small or altogether lost, the author is of opinion that the granular condition represents the last stage in the development of these bodies. The form and the size appear to differ considerably as we pass from one species to another; the form, which is always ovoid, appears to be permanent so long as the blood is retained within the circulatory cavities; as an example of this we may cite the case of *Palæmon*, where the leucocytes found in the lateral lobes of the telson did not, during a long period of examination, exhibit any amœboid changes.

Pyloric Ampullæ of Podophthalmate Crustacea. *—F. Mocquard describes the ampullæ as forming the floor of the median part of the pyloric duct; in most cases they may be compared to two demi-cylinders placed side by side, with the cavity upwards. The surfaces are not, however, regularly cylindrical, for they are rounded and truncated obliquely behind. Their inner edges unite to form a projecting longitudinal—*interampullar*—fold; from their cavities and from the sides of the fold there arise a large number of parallel longitudinal crests, on the free edges of which there are rows of extremely fine setæ; from this arrangement there results a considerable number of small prismatic canaliculi, directed from before backwards; the free edge of the posterior portion of each of these ampullar crests is continued into a large seta, which is directed backwards and carries extremely fine setæ. A remarkable point in this arrangement is that very slight differences are found even when the Stomapoda are compared with the Decapoda. Similar ampullæ are to be seen in the larvæ (and doubtless also in other forms) even when there is no gastric armature; while further, though absent in the *Mysis*, they are to be found in the Mysis-stage.

We never find any appreciable amount of food in the ampullar cavities, and their functions would appear to be this: while the nutritious matters which are difficult of digestion remain in the superior portion of the pyloric duct, the more finely divided particles make their way between the interampullar fold and the side-wall of the pylorus along a line parallel to, but in a contrary direction to that of the setæ; they are thus broken and brought into a sufficiently fine state to enable them to penetrate into the canaliculi, whence they pass backwards in a longitudinal direction. In support of this view, the author directs attention to the fact that the excretory ducts of the so-called liver empty their products not far from the posterior orifice of the canaliculi, where the alimentary matters and this secretion would therefore be brought into intimate contact.

* Comptes Rendus, xciv. (1882) pp. 1208–11.

Heterogeny of Daphnia.[*]— C. L. Herrick, in the course of researches upon the development of *Daphnia Schaefferi* (= *magna*), observed several interesting facts.

The embryo, before leaving the egg, in both summer and winter forms, is furnished with palpi on the base of the second antennæ, and a long appendage from the dorsal region of the shell. The former, though quite large in the embryo, is later nearly atrophied, remaining during life, however, as a wart-like process with two rather small spines. The latter is curved beneath the body, lying between the valves of the shell. After the escape of the animal from the egg this organ becomes the dorsal spine, and seems to serve as an aid to the complete moulting of the walls of the brood-cavity, with the first development of which the spine seems also to stand in intimate relation.

It is worthy of remark that not only the mature animal, after long confinement in aquaria, becomes smaller and stouter, and in other peculiarities resembles the smaller spined species of *Daphnia*, but that the young retain the dorsal spine and the shorter form till in a sexually mature condition, when in confinement. This fact, and the discovery of Dr. Birge, that the spine upon the head of another species of *Daphnia* is also an embryonic organ, serve to call attention to the systematic position of this genus. It would therefore appear that the species *Schaefferi* is the culmination of a cycle of forms, among which are to be counted more or fewer of the species described as distinct.

Daphnia thus furnishes another example of so-called "Heterogeny."

Notodelphyidæ.[†]—W. Giesbrecht describes the female reproductive organs of these parasitic Copepoda. The ovarian tubes are completely differentiated before the last ecdysis, when they present the following features; there is a structureless *tunica propria* lined by a simple epithelium, the cells of which are as broad as high. As changes occur, this epithelium becomes separated off from the wall of the tube; the process commences at the anterior end, and gradually passes backwards, so that in a series of sections the anterior ones are filled with the separated cells, while the lumen of the hinder ones is still open and the wall invested by epithelium; the cells do not break off separately but in longitudinal rows. When this process has come to an end, the walls of the tube are formed by a distinct membrane, which is lined by a layer of protoplasm; at first the nuclei in this latter are at some distance from one another, but they soon come to form groups of two to six. The tube, therefore, first had the function of a germ-producer, and may be called the *ovary*, while, later, it serves as an *oviduct*, and affords nutriment to the growing ovarian cells. Owing to their coming off in longitudinal rows, the ova now lying in the tube are arranged in cords of a cylindrical form, each of which may have as many as one hundred eggs; there is no investing membrane to these ovarian cords. A little later the

* Zool. Anzeig., v. (1882) pp. 234–5.
† MT. Zool. Stat. Neapel, iii. (1882) pp. 293–372 (3 pls.).

separate cells begin to be distinguished from their neighbours; many of them increase in size by the growth of their peripheral portion, and the internal contents of these do not therefore become altered in character. Others develope within themselves fatty bodies. Under the influence of the growing ova the paired portions of the ovarian tubes increase greatly in diameter, and soon after this the eggs make their way into the maternal cavity, where they pass through the stages of development prior to the Nauplius condition. The dorsal folds are chiefly formed of a connective tissue, which consists largely of membranous elements and partly of spindle-shaped fibres, which may be regarded as muscle-cells; in addition to these there are rounded fibres, which extend from one surface to the other. Rounded or ellipsoidal bodies are to be found lying in the meshes of the tissue, filled by a very regularly arranged polyhedral meshwork of very delicate membranes. A number of fatty cords traverse the appendage in a radial manner; these are processes of the fat-body which is so frequently found in parasitic Crustacea and are here particularly well developed. The investing membrane is a continuation of the general chitinous covering of the body, though it is here more delicate than in other regions. As there is in all essential points the very closest agreement between the structure of these folds and that of the other parts of the body, it would be better to speak of them as processes of the body-cavity, than as dermal folds. The specially modified portion which serves as a brood-pouch has its internal lamella formed by a specially thick chitinous membrane, and is at first so folded as to allow of the increase in size of the cavity which becomes necessary later on.

Some of the habits of these forms are treated of in detail, and it is pointed out that the first copulation commences before the final ecdysis of the female, but the attachment of the spermatophores only becomes completed after the ecdysis; in this action of the male, the appendages, and specially the fourth or fifth pair of feet, take part. Various males may fertilize the same female who remains completely passive during the whole act. The reason of this apparently premature copulation is considered, and the suggestion is made that it is an arrangement derived from an earlier condition in which the female did not pass through the last ecdysis.

The succeeding acts of oviposition and delivery are described; they are repeated at regular and constant intervals, whereas the later acts of copulation are not so definitely arranged. A female who has just deposited her ova, has a thin, faintly-coloured, hardly detectable ovarian tube; five days afterwards this is again filled, and the red eye-spots of the embryos in the brood-cavity can be made out. After ten days from oviposition, the embryos are ready for extrusion, and again the ovarian tube will be found full; for about two and a half days the brood-pouch remains empty.

The author does not look upon the development of the fat-body as an arrangement which owes its origin to the struggle for existence, but as a passive necessary result of the parasitic habits of these animals; the assimilated nutriment which the free-living forms use

up owing to their activity, has no use in an organism which lives a parasitic life; and the physiological process is therefore completely similar to that which obtains in fattened cattle.

The earlier part of the paper is taken up by (1) an account of the presence of these forms in certain Ascidians, the author only finding them in *Phallusia mentula*, and *P. mammillata*, where they are far from being the only guests; (2) a description of their external form; and (3) a systematic account of the species, which are arranged under the genus *Doropygus*, with as subgenera, *Doropygus* and *Notopterophorus*. Seven species appear to be known.

Organization of Trilobites.*—The veteran H. Milne-Edwards, in discussing the results of the researches of Mr. Walcott,† concludes that the alliance, on which he long ago insisted, between the Trilobites, Isopoda, and Phyllopoda, is strengthened rather than weakened by these studies; he cannot believe that they were representatives of the Arachnidan type from which the *Limuli* appear to have been derived, and he thinks that a group composed of Trilobites, *Limuli*, and Eurypterina would be altogether artificial and inadmissible into a natural zoological classification.

It is pointed out that although there is, at first sight, a very considerable resemblance between young *Limuli* and young Trilobites, yet that the latter soon become provided with thoracic segments, and, to cite characters of less importance, they tend to become ornamented with those long spiniform prolongations, the presence of which is so characteristic not only of Zoeæ, but of many adult Macroura.

If we examine the respiratory organs of the Trilobites, we find them to differ much more from the *Limuli* than they do from the Branchiopoda or the Hedriophthalmata. The principal differences between the external structure of a *Limulus* and of a Phyllopod or an Isopod are to be found in the relations of the mouth to the appendicular system, and the mode of division of labour between the different parts. In the *Limuli* we find two distinct groups: one forms a masticatory, prehensile, and ambulatory system, at the centre of which we find the mouth; the other, the respiratory apparatus, is situated more posteriorly, and presents none of the characteristic forms of any Arthropod walking limb; no known existing animal has a similar structure, and no one of the recently observed facts leads us to see any close resemblance to them in the Trilobites. Prof. Milne-Edwards has now no doubt as to the existence of a long series of post-cephalic limbs in the Trilobites, and the characters of these appear to him to present a certain resemblance to those of *Apus*; it is possible that they were almost altogether homomorphous and natatory rather than ambulatory. It is pointed out that we have an erroneous idea of the essential characters of the appendicular apparatus of the Phyllopoda, if we imagine that they are always entirely soft and membranous; in *Apus* the coxopodite and some of the succeeding joints of the internal ramus are thick and firm, and we can imagine that under the

† See this Journal, i. (1881) p. 736

effects of fossilization nothing but the parts of this internal ramus might be left to be preserved.

Vermes.

Chemical Composition of Tubes of Onuphis.* — Professor O. Schmiedeberg finds that the tubes of this Annelid consist not only of a mixture of albuminoid substance and of potassium and sodium, but of a special body (onuphin) made up of organic and inorganic bodies ; the presence of this body may be explained by the view of Ehlers that the tube is a secretion of the separate segments of the animal, a view which is based on the plentifulness of the secretion of certain glands. The question of the origin of the chemical components is considered by a reference to the quantitative analyses of various sea-waters, and it is pointed out that the striated structure of the tube is due to the different layers being separated by an albuminoid substance. The question of their food is not yet satisfactorily settled, nor have we yet the necessary knowledge of the exact constitution of onuphin.

Nematoid Hæmatozoon from a Camel.† — Dr. T. R. Lewis, recalling the fact that the occasional presence of nematoid organisms in the blood of various animals has long been ascertained, and that ten years ago he had shown that in India a somewhat similar condition was observable in man (associated with certain forms of grave disease), points out that an important contribution to our knowledge of the hæmatozoa of the lower animals has been made by Dr. G. Evans, the head of the veterinary department of Madras, who, whilst making a post-mortem examination of a camel, found that the blood of the animal swarmed with the brood of a nematoid parasite resembling the hæmatozoon of man. Dr. Evans found, further, that the parental form existed in the lungs, the pulmonary arteries of which were plugged by tangled masses of the thread-like parasites. They were also found in the mesentery.

A comparison of these hæmatozoa with those found in man shows that, whereas the embryonal forms of both kinds are indistinguishable under the Microscope, nevertheless the mature form as met with in the camel differs, both as to size and structure, from the only male and female specimen of the mature form met with in man which has hitherto been obtained in India ; and so far as Dr. Lewis is aware, this hæmatozoon of the camel differs from any hitherto described parasite. Should further inquiry confirm the supposition that the parasite is new to science, he proposed that it should be called *Filaria Evansi*. A preliminary description is given of both male and female forms.

Development of Marine Planaria.‡ — Among other important points, Prof. E. Selenka here discusses the affinities of the Planaria to the Ctenophora and the Nemertinea. We find a considerable

* MT. Zool. Stat. Neapel, iii. (1882) pp. 373-92.
† Proc. Asiatic Soc. Bengal, 1882, pp. 63-4.
‡ Zool. Studien, ii. (1881) 44 pp. (7 pls.).

though not complete similarity in developmental history between the Planaria and the Ctenophora. In both cases (1) the endoderm arises as four large pale cells, and this layer gives rise to a quadri-radiate enteron, which is permanent in the Ctenophora, but modified in the Planaria. (2) The gastrula arises by epiboly, and the blastopore and permanent mouth are coincident in position. (3) Stinging cells are to be observed in both. (4) The embryo has in both a predominantly radial (symmetrical) arrangement, but in both this is later on more or less completely modified into a bilateral symmetry. On the other hand—(1) There does not seem to be in the Planaria more than a feeble indication of an aboral sensory capsule with otoliths, such as seen in the Ctenophora. (2) A complete investment of cilia is but rarely found in the Ctenophora, e. g. embryo of *Eucharis*. (3) Nothing comparable to the eight ctenophoral plates of the Ctenophora can be detected in the Planaria. The relations of the Ctenophora and the Planaria are hardly to be doubted.

Turning to the Nemertinea, we find that in these the quadri-radiate symmetrical cleavage is confined to the very earliest stages, the endodermal cells are small, and there is no kind of communication between the enteron and the cœlom; on the other hand, stinging organs are to be found on the proboscis, the blastopore and permanent mouth are coincident, and, in fine, the Planaria in some cases present intermediate conditions between the Nemertinea and the Ctenophora.

The chief objects of the author's investigations have been *Leptoplana tremellaris*, *L. alcinoi*, *Eurylepta cristata*, and *Thysanozoon diesingi*.

Eyes of Planarians.[*]—Former investigations [†] having done little more than elucidate the *external* characters of these organs, J. Carrière has applied himself to determining their intimate structure, especially that of the nervous elements. The method employed was preservation by Lang's method, viz. a liquid composed of chloride of mercury 5 parts, glacial acetic acid 5 parts, water 100 parts; after twenty minutes or half an hour the specimen was transferred to alcohol of 70 per cent.; sections were made and stained with picrocarmine.

In *Planaria polychroa* there is an optic ganglion immediately in contact with each eye, on its outer side, and consisting of an external layer of nuclei resembling those of the cerebral ganglion, and about ·008 mm. in length, enclosing a larger mass of fine fibres. Among these fibres are some which are strongly refractive, and pass in straight lines inwards, swelling out, and ending in rather broad knobs within the pigmented hollow ("pigment-cup"), and which they probably fully occupy in life. The pigment mass consists of small globules, varying in size from $\frac{1}{1000}$ to $\frac{4}{1000}$ mm. in diameter. The eye of *Dendrocœlum lacteum* is double; the pigment-cup is single, but has two posterior openings instead of one. The eye of *Leptoplana tremellaris*, described by Keferstein in very different terms, appears, however, to agree

---

* Arch. Mikr. Anat., xx. (1881) pp. 160–74 (1 pl.).
† See this Journal, i. (1881) p. 605.

essentially with those just described. Study of pathological and abnormal specimens appears to show that the large eyes of the two former Planarians have been developed from aggregations of small ones, each consisting of a nervous cell invested by pigment; such eyes, in fact, appear in some cases as accessory appendages to the main organs. *Polycelis nigra* has the margin of the anterior end of the body beset with pigmented ocular organs, which are often united together in twos or threes. Their structure differs, however, very widely from that of the eyes of *Planaria polychroa*. Each eye consists of a homogeneous sphere, invested on its posterior side with a pigment-cup of distinct granules, which is open in front; in contact with the back of the latter organ is a large transparent hemispherical nucleated cell. The eye appears to be surrounded by ganglion-cells whose nuclei are distinct, but whose exact relations to the eye have not been made out.

Development of the Orthonectida.*—C. Julin, although agreeing with Metschnikoff in regarding *Rhopalura ophiocomæ* and *Intoshia gigas* as the male and female forms of the same species, has never been able to detect them both in the same Ophiurid. When an *Amphiura squamata* infested with males is opened there escape hundreds of individuals in different stages of development. After the first cleavage one of the blastomeres is very much larger than the other, and is more opaque; this is the ectodermic while the other is the endodermic globule. The former gives rise to as many as fourteen cells before the latter divides at all; thus there arises a condition of epiboly, where the endodermic cell is ovoid in form and has its long axis parallel to that of the embryo; the enclosed cell now undergoes division, and gives rise to a small cell at either end; one of these occupies the orifice of the blastopore. These small cells now divide into six and four respectively, and the ectoderm becomes completely ciliated; as the embryo elongates the small cells increase in length, and becoming fusiform completely envelope the central endodermal mass; in the adult they form the longitudinally striated fibres. Meantime, the central endodermic cell has divided into a large number of smaller cells, each of which contains a fragment of the primitive endodermal nucleus; each of these gives rise to a spermatozoon. Although the primordial muscular cells have been given off from it, the central cell still possesses a true membrane, which persists during the whole life of the animal and forms a pouch for the contained spermatozoa.

While the males are free the embryonic females are connected together by a granular mass (the sporocysts of Giard, plasmodial tubes of Metschnikoff). There would appear to be very great difficulties in the study of their earlier stages owing to this mode of connection. But here also there is ectodermic epiboly, though the endodermic cell divides earlier to give rise to a mass of polyhedral cells, surrounded by a layer of cubical non-ciliated cells. Later on these peripheral cells become cylindrical, and still later they form a com-

* Bull. Sci. Dép. Nord, iv. (1881) pp. 309-18.

plete but very delicate layer of fibrils, apparently comparable to the muscular layer found in the corresponding position in the male. The central polyhedral cells give rise to ova. There is, therefore, an essential agreement between the developmental processes of the male and female.

The male products escape, by the rupturing of their investing wall, into the muscular layer, where a passage is found for them ; the ectoderm undergoes change and atrophy, and the spermatozoa make their way out. The ectoderm of the female breaks off at a non-ciliated region at the anterior end, and thus the ova escape. There is another female form which seems to divide into two or three pieces, and which is distinguished by being flattened, and not cylindrical.

The females, when mature, appear to leave one host to swim in the water and to enter another, and there is some reason to believe that the cylindrical forms give rise to the males, while the flattened forms would seem to be the parents of the females. These latter possibly arise by parthenogenesis.

The author promises a fuller paper, in which he will give more details and full reasons for his belief that the Orthonectida belong to Van Beneden's group of the Mesozoa, and he concludes with an objection to the application of the terms metamere or segment to these creatures, as the segmentation is superficial, affecting only the ectoderm, and the number of segments does, it is allowed, vary.

Eyes of Rotifers.—Referring to his note read at the June meeting of the Society,* Mr. Badcock writes (July 17) :—" Yesterday for the first time I discovered eyes in a group of adult *Floscularia cornuta*, and saw them again very distinctly in *Stephanoceros eichhornii*. It seems to me desirable to put on record the fact that the eyes are found in the adult forms of *Melicerta ringens*, *M. tyro* or *tubicularia*, *Floscularia cornuta*, and *Stephanoceros eichhornii*, in all of which the eye is ignored in the usual descriptions and drawings. The eyes are not *readily* seen, but I have had some very fine specimens, and may be able eventually to demonstrate their existence in all the forms in which they were supposed to have been lost."

Echinodermata.

Anatomy of Holothurians.†—E. Jourdan finds in the connective tissue of the integument of these Echinodermata elements forming a plexus; they are coloured grey by osmic acid, are rarely isolated, and are very often united into bundles. They arise from nerves which penetrate into and extend through the skin. The fibres of this nervous plexus are accompanied by nuclei, which are chiefly found at the points of interlacement of the fibres. These fibres are very fine, slightly varicose, and accompanied by fatty granulations. The nervous centres consist of fibres and cells. The latter are frequently, though not always, unipolar.

The muscular elements of Holothurians are made up of fibres

---

* See this Journal, *post*, Proceedings.
† Comptes Rendus, xciv. (1882) pp. 1206–8.

which are remarkable for the irregularity of their form and their length. They are always provided with one or more nuclei, which are always lateral in position, large in size, and attached to the fibre by a delicate sarcolemma. The walls of the Polian vesicles consist of an outer layer of flattened cells, which recall the endothelial lymphatic cell; a layer of connective tissue in which the fibres are longitudinal; a layer of circular muscular fibres, which are very long, and have the appearance, when extended, of elastic fibres, in a state of contraction. They present a number of swellings. Within this there is a layer of epithelial cells.

Hybridization of Echinoidea.*—R. Koehler finds that, at Marseilles, the genital glands of most species are mature in March or April. In making experiments, however, it is necessary to assure oneself by microscopical examination that the elements are ripe, and with the crossing experiments it is right to fecundate by their own spermatozoa the ova of the species treated. When the ova of *Strongylocentrotus lividus* were fecundated by *Sphœrechinus granularis*, the *Pluteus* was regularly and perfectly developed. The same happened when the male was *Psammechinus pulchellus*. When the male was *Dorocidaris papillata*, the eggs did not pass beyond the blastula-stage, but the spermatozoa used were here somewhat inactive. A female *Strongylocentrotus* is not always fecundated by a male *Spatangus purpureus*. Sometimes, however, even the gastrula-stage may be reached.

Other examples are given, and the whole shows that cross fecundation is possible, within very wide limits, among the species of the Echinoidea; while the *Pluteus* derived from the crossing of two regular Echinoids may not differ much from the normal Pluteus of the female in the experiment, there are certainly well-marked differences between the legitimate Pluteus of a *Spatangus* and the hybrid Pluteus of that and *Psammechinus*. While the ova of one species may be fertilized by another, the reverse may not hold true.

Variation in Asterias glacialis.†—Professor Jeffrey Bell describes " six sets at least " of forms of this species. In the simplest there is never, in addition to the median row of spines along the back of each ray, anything more than a single isolated rather small spine on either side. Passing through forms in which there may be a few of these intermediate spines, or a larger number, we get to those in which there is a distinct row on either side of the now less conspicuous median one : two rows may be indicated on either side, or may be conspicuously developed. All the forms selected came from the coasts of Portugal, the Azores, or Madeira. It is pointed out that the character and arrangement of the pedicellariæ depends on the distribution of the spines, and it is, in conclusion, suggested that in the history of the Asteroidea the next point to work out " is the nature

* Comptes Rendus, xciv. (1882) pp. 1203-5.
† Zool. Anzeig., v. (1882) pp. 282-4.

of the sea bottom, of the surroundings, of the food, and of their enemies, as determining the strength, size, and disposition of the abactinal spines."

Cœlenterata.

Development of Calcareous Skeleton of Asteroides.*—G. v. Koch having observed that between the crystalline calcareous substance which forms the septa of *Mussa* and the hyaline connective substance that surrounds it, there are cells which form a continuous layer, asked himself whether these cells secrete the calcareous skeleton, and do they belong to the connective substance (mesoderm), or are they ectodermal in origin, and, therefore, a secretion from the primitively external surface, which is only apparently internal?

To resolve these questions he has studied the development of the skeleton in *Asteroides*, where he finds that the first indications are only to be observed some time after the larva has become fixed. These appear as a circular disk with a cavity in the centre, consist chiefly of carbonate of lime, and are composed of spheroidal pieces, made up of concentrically arranged layers. The spheroids are larger in the centre, and decrease in size as they approach the margin of the disk. This earliest skeletal rudiment lies between the lower layer and the ectoderm of its aboral surface. The cells of the latter, like those of all other parts of the surface of the body, are cylindrical, and no calcareous concretions are to be observed within them. From these facts the author concludes that the first rudiment of the skeleton is neither a product of the endoderm nor of the connective substance (mesoderm), but that it is a secreted product of the ectoderm. The further development of the skeleton is brought about by the completion and enlargement of this basal disk, and by the formation of septa. The former is effected by the formation of new spheroids, by growth, and by subsequent fusion; the septa arise from radial endodermal ridges which attain a considerable size. Later on, the ectoderm enlarges, and there appear calcareous secretions, formed of small crystals, which fuse with the disk, and form the first rudiments of the septa. In the next stage the septa are higher and begin to branch at their peripheral ends. Growing still more, they broaden out, partly into the form of thin lamellæ, get small spinous processes, and fusing at their peripheral ends with one another form the theca. The columella is similarly formed by a fusion of the central ends. While these changes have been going on there is a further secretion of carbonate of lime at the free edge of the young *Asteroides*. This unites with the aboral disk, and gives rise to a thin lamella. This is the epitheca of authors, and it is important to note that at first it is completely separate from the theca, and that it only secondarily becomes connected with it. Very little now remains to be observed, except the growth of the septa, theca, columella, and epitheca. We may remark, however, that from the primitively twelve septa there soon arise six which are stronger than the rest, and, alternating with them, appear to give rise to two cycles; twelve new septa

* MT. Zool. Stat. Neapel, iii. (1882) pp. 284-92 (2 pls.).

also begin to appear. Still later on, it may be seen that the septa form three or four cycles, which consist respectively of 12, 12, 24, and 48 pieces; the younger always appear between two older ones.

Development of Æquorea.*—Prof. C. Claus states that *Æquorea forskalea* deposits its ova in March. They are without an investing membrane, and are deposited in great quantities. The directive corpuscle is soon expelled, and just below the point at which it escaped a clear vesicle may be seen in the yolk for a few hours afterwards. The central cleavage-cavity is open at both ends until the 16-sphere stage. Later on, when these become closed, the region of the upper pole may be still distinguished by the greater thinness of the walls of the hollow sphere at that point. As the cells become smaller, cilia appear on the surface, and the mass begins to rotate. It soon, however, elongates, and becomes narrower near the lower pole, which is now posterior. The cells of this region become much higher, and gradually form a projecting process into the cleavage-cavity. Some of the more internal cells break away, and form isolated spheres within that space. This process goes on until the whole becomes filled with small cells, which represent the endoderm. At first there is distinct continuity between the endodermal cells, and the ectodermal from which they have arisen. On the third day the embryo presents all the characters of a *Planula*, and swims freely about. Stinging cells appear, and the long axis of the body is marked by a somewhat irregular line, which is the optical expression of a cleft in the endoderm. On the fourth and fifth days this cleft becomes wider and filled with dark granules. In this condition the larva swims about freely for some time. Fixation has not been directly observed.

This polar ingrowth of the endodermal cells is not any kind of delamination, but has, as the author hopes to show in a further communication, a not distant connection with the other mode of development, which is known as that of invagination.

Porifera.

Hybridization in Fresh-water Sponges.†—Mr. E. Potts, in exhibiting some fragments of fresh-water sponges collected in the Boston Aqueduct, consisting of, it is believed, *Spongilla paupercula* and a new species, *Meyenia acuminata* (with others), points out the following exceptional features as marking the collection: (1) that all the statospheres, whether belonging to *Spongilla* or *Meyenia*, were *smooth*, that is, without a granular or cellular "crust"; (2) the apparent absence of dermal spicules in both, and the abnormal character of these belonging to the statospheres. The appearance is not infrequent, but has, so far as known, heretofore been limited to the genus *Spongilla*. The recurrence of the same feature in the associated genus *Meyenia*, coupled with the fact that many of the birotulates upon its statospheres were imperfect, the rays being more

---

* Zool. Anzeig., v. (1882) pp. 284–7.
† Proc. Acad. Nat. Sci. Philad., 1882, pp. 69–70.

or less aborted approximating their shape to that of the spined fusiform acerates of *Spongilla*, gave rise to the suggestion that here, possibly, had been, not merely a mechanical mixture by inter- or super-position of species, but an organic hybridization produced by the flowing together of the amœboid particles of which the sponges are composed, or even by a fertilization of the ova of one by the spermatozoids of the other.

It is important to note that the specimens were collected in February, when the sarcode matter had nearly all been washed away with, probably, accompanying changes in the presence or numbers of the smaller spiculæ.

Boring Sponges.*—Mr. J. D. Hyatt, referring to papers in the Journal of the Quekett Microscopical Club (in which the question is discussed whether *Cliona* forms the burrows in which it is found or whether they are excavated by annelids or other animals), is convinced that there is one weak point characterizing all the observations, which invalidated to a great extent the conclusions on both sides. This was, that dried specimens had been used, or, as one author mentions, the live sponge occupying old shells and rocks. It occurred to him that a study of the live sponge occupying the shells of healthy, living molluscs, might present evidence for one side or the other that had hitherto been overlooked, and he therefore procured some oysters, a considerable number of which had shells tenanted by *Cliona*.

An exhaustive microscopical examination of these and similar specimens, seems to him to establish, beyond a possibility of doubt, that the sponge is, in this case at least, the only factor to be held accountable for the burrows. The outer layer of the shells was punctured with numerous holes, often many hundred, varying from the $\frac{1}{20}$ to the $\frac{1}{100}$ of an inch in diameter, generally occupied by the osculæ of the sponge. Between the outer and inner layers, and extending laterally, the shell was almost entirely excavated, and the space occupied by the sponge and its numerous spicules; while extending inward from this sponge-mass were innumerable minute, branching and ramifying burrows, uniformly and completely filled with corresponding arms of sponge, many of which extend quite through the interior layer of shell. The contact of these arms with the external membrane of the oyster causes the latter to deposit at such points an additional amount of lime carbonate, and the interior surface of such shells presents the appearance of numerous little prominences caused thereby.

The only possible theory that will account for these burrows, if they are not made by the sponge, is that they are the deserted excavations of worms; but this theory is untenable, as it would be necessary to suppose that the shell was once inhabited by an innumerable multitude of such worms; otherwise the perforations through the inner cell would have been closed, and all of these must have retreated at the same time, so completely that no trace of them could

* Amer. Mon. Micr. Journ., iii. (1882) pp. 81–4 (3 figs.).

be found, and the sponge must then have extended its growth into the deserted channels with such rapidity as to fill every minute branch before the oyster could bar it out by the secretion of enough new shell to stop apertures $\frac{1}{1000}$ inch diameter.

But this is not all. The burrows occupied by *Cliona* branch in all directions and diminish in diameter as they extend inward, which would represent a method of boring quite inconsistent with the habits of any known borer. Again, in these specimens, the sponge was found in small spots on the thin laminæ, around the sides and anterior edges of the shell which represent its most recent external growth, and in such cases the laminæ were perforated from side to side.

Protozoa.

De Lanessan's Protozoa. *—This will be found a welcome book by microscopists, as it is copiously illustrated with woodcuts and deals with the subject in a very readable form, while yet being far beyond a merely popular handbook.

The author's leading divisions are Monerans, Amœbans, Foraminifera, Radiolaria, Infusoria (flagellate, ciliate, and tentaculate), and he claims to have originated a new plan for such a book differing from that of ordinary treatises. He commences in each case with considering in its adult state an individual species chosen as the best type of the group (by its being readily procured, best known, &c.), dealing with all the details of its organization, with its physiological functions, its habits, and the development of its organs, considerable importance being given to embryology. He then describes the other leading forms of the group, and when all these have been disposed of a separate chapter sums up the common characters of the group, its relations with neighbouring groups, and its classificatory divisions.

The author considers that a great mistake is made when the converse course is adopted and the characters of the group are dealt with, noticing the peculiarities of the organization of the different types of the group in the course of the general description. By this method, he says, " a Mollusc becomes a kind of abstract entity clothed with characters rendered so vague by the generalization that the student has the greatest difficulty in discovering them in the specimen given him to dissect."

Taking the Amœbans for an example the following is the author's arrangement :—

1. The principal forms.

(*a*) Gymno-Amœbans. Under this head are described *A. princeps, A. coli, Podophrys elegans, Pelomyxa palustris, Dactylosphærium radiosum, D. polypodium, D. vitreum, Hyalodiscus rubicundus, Petalopus diffluens, Plakopus ruber, Podostoma filigerum,* and *Mastigamœba aspera* (9 figs.).

(*b*) Theco-Amœbans.—*Pseudochlamys patella, Cochliopodium pellucidum, Difflugia oblonga, Quadrula symmetrica, Arcella vulgaris,* and *Amphizonella violacea* (6 figs.).

* J. L. De Lanessan, ' Traité de Zoologie. Protozoaires,' vii. and 336 pp. (281 figs.) 8vo, Paris, 1882.

2. Common characters, classification, and affinity.

The author defines Amœbans as Monerans which have acquired a nucleus and contractile vacuoles, and distinguishes 17 genera, a third group of flagellate Amœbans being here formed of the genera *Mastigamœba*, *Reptomonas*, and *Rhizomonas*.

Kent's Manual of the Infusoria.—This is now completed by the issue of the 6th part and forms a magnificent monograph of the Infusoria which cannot fail to be of the greatest value and assistance to the microscopist.

The concluding part has an appendix containing a notice of species recorded during the publication of the work, a glossary of technical terms, an extensive bibliography of the Infusoria, and a plate illustrating the apparatus employed by Messrs. Dallinger and Drysdale and by Professor Tyndall in their investigations on Monads, &c.   The plate also contains a figure of a Microscope and lamp arranged for working with high powers, the Microscope being horizontal and the lamp turned with the narrow edge of the flame towards the condenser.   The plan described is by no means the novelty which it is suggested to be; it is, in fact, the one adopted since the days of Quekett for all delicate high-power work.

Flagellata.[*]—In a previous communication J. Kunstler[†] recorded the results of researches undertaken on the Flagellata, to which more recent observations enable him to add some new facts.

Cryptomonas ovata Ehrbg., after being submitted to the action of acetic acid, appears to be covered with filaments; Bütschli, who has described analogous productions in *Chilomonas paramœcium* Ehrbg., considers that they are trichocysts, that is, organs of defence comparable to the nematocysts of Cœlenterata; the author, however, has never been able to see in this organism the small rods which are so abundant in the integuments of certain ciliated Infusoria, and within which, if the comparison with urticating organs is correct, the attenuated prolongations should at first be enclosed.   The filaments, incomparably more numerous than those which have been figured by Bütschli, form a thick peripheral layer, and their length is often enormous, thus there are some ten times the length of the body; generally they take an upward inclination.   At the upper part of the body, on the prolongation of the posterior margin of the hollow in the digestive chamber, two or sometimes three of these prolongations may be observed which are thicker, longer, and more rigid, whilst the others are often slightly flexible.   *Cryptomonas erosa* also has these filaments.

In the cold season, *Cryptomonas ovata* acquires special characters. The nucleus only contains the large nucleolus.   The cuticle is generally very thick over the whole surface of the body, and the vacuoles in it are very easily visible without the intervention of any reagent; in certain points this cuticle presents a very considerable development, for example at the lower extremity where it forms a

---

[*] Comptes Rendus, xciv. (1882) pp. 1432–3.
[†] Ibid., xciii. (1881) pp. 746–8. See this Journal, *ante*, pp. 62–3.

prolongation directed backwards, or better at the dorsal rostrum (which is itself prolonged) where it often forms a long point. It also presents, besides the line devoid of green colouring matter, the existence of which on the left face the author has already recorded, another, colourless, tolerably broad, longitudinal line through the whole length of the right face. Finally the starch-grains of the deep mamillated layer are rarer and very thin; but extending over almost every part of their body are seen some irregular more refringent corpuscles resembling concretions, which are perhaps also formed of starch, although they do not turn blue under the influence of iodine.

In an infusion that was in an advanced state of decomposition the author has met with *Chilomonas paramœcium* Ehrb. in a sort of palmelloid state; a number of individuals of this species being united in a common transparent gelatinous mass, having a great resemblance to a *Zooglea.* Cienkowski has observed an analogous phenomenon in *Cryptomonas polymorpha*, and was confident that it was a mode of reproduction. The author has never observed this phenomenon except in cultures which were more or less putrefied and placed in unfavourable conditions with regard to light; these organisms are always isolated and very active in clear water well exposed to the light. *Astasia costata* has a muscular, subcuticular layer with spiral fibrillæ analogous to those in the *Euglenæ.* The contractile vesicle of *Phacus pleuronectes* Duj. has distinctive vacuolar walls resembling those of the analogous organ in *Cryptomonas.* The terminal flagellum of *Monas vinosa* Ehrbg. that Cohn considers to be merely the mobile spore of *Clathrocystis roseopersicina* (a chromogenous bacterium), displays a transverse striation when it has been submitted to the action of reagents that colour strongly.

Cell-parasite of Frog's Blood and Spleen (Drepanidium ranarum).[*]—In 1880 we referred [†] to a discovery made by Dr. J. Gaule of certain *Würmchen* or "vermicles" in frog's blood, which he considered to be simply protoplasmic portions of the corpuscles separated for a short independent life, and not parasitic organisms. Prof. Ray Lankester now points out that these are, in fact, the minute, sausage-like parasites, discovered by him in 1871 (for which he proposes the name of *Drepanidium ranarum*), and that they are clearly parasitic organisms, probably the young stage of a sporozoon allied to *Sarcocystis* or to *Coccidium.*

Some of the chief observations of Dr. Gaule are, in fact, directly favourable to the view that the *Würmchen* are independent parasitic organisms, for (1) they exhibit active movements under circumstances usually favourable to the movements of the Protozoa and Protophyta; (2) they occur within the cells of the organism in which they are found as well as in its fluids; (3) they are present in some frogs and not in others living under approximately the same conditions; (4) they vary in abundance in the same frog, examined at different times;

---

[*] Quart. Journ. Micr. Sci., xxii. (1882) pp. 53–65 (5 figs.).
[†] This Journal, iii. (1880) p. 232.

(5) they are abundant in one time of the year and not at another; (6) they are seen on the stage of the Microscope to penetrate and enter cells by means of their active movement ; (7) they are also seen to escape from cells by the same activity ; (8) they are localized chiefly in the spleen though not confined to that organ ; and (9) though most abundantly observed in certain specimens of *Rana esculenta* at Leipzig, yet they have also been observed in *Rana temporaria* and in *Triton* sp.

These observations are not merely consistent with the view that *Drepanidium* is an independent parasitic organism, but are directly in favour of that view, since they are readily explained if that view be admitted, whilst they remain as isolated and unconnected facts, each requiring a special assumption for its connection with any other theory which may be advanced as to their nature, when the obvious one that they are parasitic organisms is rejected.

The only fact which Dr. Gaule adduces which is inconsistent with the parasitic nature of *Drepanidium* is that in some cells, especially blood-corpuscles, these bodies are not present when an examination of them is first made on the field of the Microscope, and that on the addition to the preparation of 0·3 per cent. solution of sodium chloride the *Würmchen* are formed there and then in the cells. Prof. Lankester, however, doubts altogether the accuracy of Dr. Gaule's statements on this point, the supposed fact being really an erroneous interpretation of an observation. Just as the nucleus in the frog's red corpuscle is frequently not visible during life and only becomes visible as the result of the first change in blood removed from the blood-vessels, so *Drepanidium* is invisible in the normal condition of the red blood-corpuscle owing to the identity of the refractive index of its delicate substance and that of the body of the corpuscle. It only becomes visible when a change in the refractive indices takes place.

Prof. Lankester suggests that researches should be directed to the discovery of a Gregariniform stage, and of cysts containing spores, or of isolated spores in which several *Drepanidia* may be enclosed. These phases in its life-history are very possibly to be met with in other regions of the frog's body than the blood-vessels or the spleen.

Development of Trypanosoma.*—Dr. J. Gaule has also re-investigated the remarkable organism of Flagellate character found in frogs' blood, the so-called *Trypanosoma sanguinis* Gruby, and puts forward a decidedly new and original interpretation of it, arriving at the conclusion that it is not an independent organism, but is produced by spontaneous modification of the white blood-corpuscles. Its production is favoured in general by warmth, hence it is found in frogs more particularly at the commencement of the warm period of the year, and it may also be seen to occur during the winter in frogs which have been kept in a warm room. These conclusions are attempted to be supported by the fact that the direct and frequent

* Arch. Anat. u. Physiol., 1880 (Physiol. Abth.) pp. 375–92 (1 pl.).

conversion of white blood-corpuscles into *Trypanosoma* (or Kymato-cytes as Gaule proposes to call them) may be observed on the warm stage.

The transmutation of the white corpuscles is said to take place as follows :— At one point in the periphery of the corpuscle is developed a vibrating flagellum from which is subsequently but gradually produced a hyaline undulating ribbon; ultimately the whole body becomes flattened out and the flagellum degenerates into a pointed process of the lobate mass thus formed. The fully developed kymatocytes show such exuberant multiplicity of forms that the writer is able to distinguish no fewer than five types among them. Conversely, however, the *Trypanosoma* have the power of being re-converted into leucocytes with amœboid movements. Gaule, according to his showing, has directly observed the process of re-conversion, which he describes, many times, and he elucidates it by pictorial representations of the successive stages.

One circumstance which appears to be of special importance in the matter is not made clear in the memoir, namely that as the white blood-corpuscles of the frog are known to be provided with a number of small nuclei, the *Trypanosoma* ought also to exhibit them, but neither are they described or do any cell-nuclei appear in the figures. This point seems to Prof. O. Bütschli [*] the more important, because in the life-history of certain Protozoa (cf. especially *Ciliophrys* Cienk.), amœboid and flagellate stages succeed one another, so that a similar alternation in the life-history of *Trypanosoma* proves nothing of itself as against their Protozoan nature. Indeed, the very point whether these amœboid bodies whose transmutation gives rise to the *Trypanosoma*, really are white blood-corpuscles, appears to Prof. Bütschli to be by no means free from uncertainty notwithstanding the present investigations. Prof. Lankester also considers [†] Dr. Gaule's views to be " devoid of justification."

New Gregarines.[‡]—Dr. R. Rössler found in the enteric canal (chiefly the cæca) of the Phalangida, among other parasites, two Gregarines which appeared to be new. *Actinocephalus fissidens* n. sp. has twelve pairs of cleft hooks on its head, and between each pair there is a simple spiniform process. *Stylorhynchus caudatus* has the " head " placed on a stalk, and provided with twelve ridges or projections, which extend beyond the margin of the head and then divide. This form is also provided with a delicate caudiform appendage, which is not separated from the body proper by any septum. In some cases these parasites were so numerous that the death of the host may be ascribed to their presence.

BOTANY.

A. GENERAL, including Embryology and Histology of the Phanerogamia.

Chemical Difference between Dead and Living Protoplasm.—Dr. O. Loew sends us a photograph illustrating his researches on this subject,* from which Fig. 90 is copied.

The upper part of the woodcut shows a filament of *Spirogyra nitida* Ktz., *killed* by a 0·1 per cent. solution of citric acid before

FIG. 90.
treatment with the silver reagent, no blackening being produced, and the spiral arrangement of the chlorophyll-bands being distinct. The lower part shows a filament when placed in the *living condition* into the silver reagent, the reducing effect of the living protoplasm on the silver-salt having converted the cell-contents into a black opaque mass.

Killing of Protoplasm by Various Reagents.†—Loew and Bokorny have applied their test for distinguishing between dead and living protoplasm, viz. its power of reducing dilute alkaline silver solutions, to determine the degree of resistance offered by protoplasm to various destructive agents. After complete withdrawal of light for five days, about 50 per cent. of the filaments of several species of *Spirogyra* still showed signs of life; it was not till the sixteenth day that all were completely killed. Twelve hours' desiccation over concentrated sulphuric acid destroyed the appearance of life in almost every cell. Triturating in a mortar destroyed life, even where there was no apparent injury. After warming in water of 46° C. for a short time, about 10 per cent. of the cells still showed signs of life, at 55° about 2 per cent.; and a temperature of 60° altogether destroyed life. Exposure of one hour to vapour of ether destroyed life except in some cells containing a large amount of oil and in spores, sugar being formed during the process. After twelve hours in chloroform-water, 5 per cent. of the cells were alive; two days in petroleum

* See this Journal, i. (1881) p. 906; *ante*, p. 67, 361, and 440.
† Pflüger's Arch. f. d. gesammt. Physiol., xxvi. (1881) pp. 50-9. See Bot. Centralbl., ix. (1882) p. 392.

destroyed all power of reaction, causing copious formation of sugar ; absolute alcohol destroys life in an extremely short time. Exposure for twenty-four hours to a stream of carbonic acid destroys the life of the cells. Hydrochloric acid and citric acid produce an injurious effect almost immediately. The power of resistance to alkalies is much greater. Immersion for one hour in a 10 per cent. solution of sodium chloride destroys most of the cells. Metallic poisons act more slowly ; some cells still show signs of life after immersion for two hours in 1 per cent. solution of sugar of lead, or for twelve hours in 0·1 per cent. of arsenic acid, or for twelve hours in 1 per cent. of zinc vitriol. Of organic poisons, gallic acid, pyrogallol, resorcin, hydrochinon, in 1 per cent. solutions, act rapidly, destroying life in a few hours, as also 0·2 per cent. salicylic acid, and 1 per cent. carbolic acid in one hour. Alkaloids, acetate of strychnin, chinin, and very dilute veratrin do not prevent the reaction, although the structure of the protoplasm is destroyed ; 1 per cent. sulphuric acid destroys the power of reaction.

Apical Cell-growth in Phanerogams.[*]—In order to determine the much-disputed cause of the want of a special apical cell in flowering plants, G. Haberlandt has closely investigated the process of apical cell-growth in the following instances : the cell-divisions of the cortical parenchyma in the laburnum and in the trichomes of the leaf-stalk of *Begonia Rex* ; the formation of the stomatal apparatus and neighbouring cells in *Mercurialis* and in Crassulaceæ ; the cell-divisions in the formation of the hypodermal bast-cambium bundle in the leaves of *Typha latifolia* ; the formation of the midrib of the leaf of *Elodea canadensis ;* and the formation of the leaves and axillary shoots of *Ceratophyllum demersum.*

The general conclusions arrived at are, that in Phanerogams there are tissues and masses of cells of very different extent and significa-tion, which have been formed by apical cell-growth. It may be either rows of cells only that increase by apical growth, as in the first and second of the above instances, or plates of cells, as in the third, or finally masses of cells may exhibit apical cell-growth, as in the two last. Each of the three tissue-systems of Hanstein, der-matogen, periblem, and plerome, grows at first by means of a single apical cell.

Development of Bordered Pits.[†]—E. Russow has carefully in-vestigated the development of bordered pits, and of the membrane of wood-cells, more particularly in the Abietineæ. The general con-clusions at which he has arrived are the same as those of Sanio. The growth of the wall of the border points to the interpretation of a kind of secondary division-wall, as if a free membrane were excreted on the upper side of the protoplasm.

Development of Tissue as a Characteristic of Groups of Plants.*— M. Westermaier thus sums up his conclusions on this subject. The results of anatomical investigations in reference to affinity differ according as the physiological idea of the subject is taken into account or not. In the latter case the result is either false or uncertain, while the former leads to a comparison on a rational basis. This last method of inquiry results in the conclusion that in the Primulaceæ the presence of a ring of bast may be regarded as an anatomical family character. In *Campanula*, while one group has in the stem the ordinary ring of vascular bundles with the phloem on the outer, the xylem on the inner side, a second group of the genus has a phloem-bundle in the pith, with or without xylem, a difference connected with physiological functions.

Stomata of Polycolymna Stuarti.†—The more or less complete fusion of two or even of three stomata into one, has frequently been noticed as an exceptional phenomenon. In *Polycolymna Stuarti* (Compositæ) F. Hildebrand states that it is so common, both on the stem and on the leaves, that it may be regarded as a normal occurrence.

The relative position of the two clefts in these double stomata varies greatly. In some cases they are parallel, in others at right angles to one another, while sometimes again one is behind the other, so that only one pore belongs to the two clefts. The mode in which the guard-cells are formed out of the ordinary cells of the epidermis appears also to be subject to great variation. The author was unable to determine whether the cells strongly charged with protoplasm divide directly into guard-cells, or whether this is only effected after repeated division ; both processes appeared to take place. The direction of the septum in consequence of which the guard-cells are formed, is also very various ; it is sometimes vertical, sometimes parallel to the wall by which the mother-cell of an epidermal cell is cut off. The occurrence of double, and occasionally of treble stomata, may be attributed to these numerous variations in the mode of their formation.

The stomata of *Polycolymna Stuarti* present also other peculiarities. The guard-cells are placed in various positions as to height in relation to the surrounding epidermal cells. Usually the outer walls of the guard-cells are about at an equal height with those of the surrounding cells, and this is almost invariably the case with double and treble stomata. But among these are others, distributed irregularly, the guard-cells of which are more or less elevated above the surrounding epidermis, this variation being possibly connected with their special function.

The number of stomata is about the same on the under and upper surfaces of the leaves; on the under surface they are protected by densely crowded glandular hairs, on the upper side by a dense felt of silky hairs. The stomata with most elevated guard-cells are found

on the under surface. They are also very numerous on the upper part of the stem, where they are also protected by glandular hairs.

Properties and Mode of Formation of Duramen.[*]—J. Gaunersdorfer gives an historical *résumé* of what is known respecting the duramen, which is distinguished by frequently containing gummy and resinous substances in its vessels or cells, as well as large deposits of carbonate of lime. His own observations he sums up as follows :—

The production of duramen takes place in consequence of the elements of the wood becoming filled by derivatives of the solid woody substance ; these products being formed to some extent in the part which becomes indurated, and partly in neighbouring portions of the wood ; by this means the extent of duramen is increased. These substances must originally be fluid and rich in tannin ; but the cells contain also other substances which give to the duramen its great power of resistance. Nitric acid or "macerating fluid," and then potash- or soda-ley, remove most of these substances, except in the case of *Diospyros*. If the induration is carried on sufficiently long, the cell-walls are also partially destroyed, and the products of decomposition mingled with the contents. The composition of the substances contained in the duramen varies with the species ; that of the Amygdaleæ, for example, contains gum (?), of the coniferæ resin, of *Syringa* resinous substances. The purpose of the duramen, at least in the lower parts of the branches, is to furnish a protection for the sound wood against the influence of atmospheric agents.

History of Assimilation and of the Functions of Chlorophyll.[†]— A. Hansen gives a list of the researches and conclusions on this subject from the days of Ingenhousz, Senebier, and Hales. The first scientific explanation of the phenomena he considers to be that of Sachs, between the years 1862 and 1865, that the starch in the chlorophyll-grains is a product of the living chlorophyll, and is produced in the chlorophyll by its power of assimilation. The author criticizes unfavourably the views of Pringsheim with regard to the nature, mode of formation, and functions of hypochlorin.

Theoretical View of the Process of Assimilation.[‡] — In his investigations on the chemical constitution of protoplasm,[§] J. Reinke was led to frame a hypothesis as to the immediate products of the reduction of carbonic acid. He points out that this gas, CO_3H_2, may be subjected to three degrees of deoxidation. By the removal of one combining proportion of oxygen it becomes formic acid, CO_2H_2, which he states is always formed in every vegetable cell. The second stage of deoxidation reduces it to formic aldehyde, COH_2, a remarkably

[§] See this Journal, *ante*, pp. 361–2.

polymeric substance, two of its isomers being oxymethylen, $C_3H_6O_3$, and glucose, $C_6H_{12}O_6$. The result of complete deoxidation is the production of methylene, CH_2, a substance which cannot itself exist independently, but which again has a very large number of isomeric hydrocarbons, as diamylene, $C_{10}H_{20}$, triamylene, $C_{15}H_{30}$, and tetramylene, $C_{20}H_{40}$; the highest members of this series being solid and crystallizable.

With this process of reduction is associated a process of oxidation in the chlorophyll-grains, and the resulting products are derived from the balance of these two processes. The most common stage of reduction reached is that of formic aldehyde.

Reinke believes that this hypothesis is in harmony with that of Pringsheim regarding the formation of hypochlorin. A portion of the formic aldehyde is reduced to the hydrocarbon condition; and the hypochlorin results from a condensation of such groups. Passing from the reducing region of the chlorophyll-grain to the respiring portion of the cell, it is there oxidized into the volatile fatty acids. Both formic aldehyde and hypochlorin are very readily oxidizable, and require the protection of the chlorophyll to prevent their oxidation.

First Products of Assimilation.* — A. Mori has performed a fresh series of experiments, chiefly on *Spirogyra*, which confirm his previous conclusion that the first product of assimilation in chlorophyllaceous plants is an aldehyde, probably formic aldehyde, formed according to the following equation out of the elements of carbonic anhydride and water:—$CH_2O_3 = CH_2O + O_2$.

Absorption of Metallic Oxides by Plants.†—Mr. F. C. Phillips says that the question how far the vital processes of plants are influenced by the various mineral compounds presented by the soil to their roots has long been under discussion, but further than to establish the fact that the presence of certain compounds in the soil tends to increase the nutritious elements and promote the growth of particular plants, little has been done towards a complete solution of the problem.

It is well known that potash tends to increase the quantity of starch, that silica strengthens the stems of the grasses, that oxide of iron is essential to the production of leaf-green, and that phosphates increase the fertility of the soil for cereals, but even as regards these constant elements of every soil, very little can be positively asserted of the precise influence of any one, in the economy of the plant.

Concerning the part played by the rarer elements, cæsium, rubidium, copper, nickel, manganese, zinc, and barium, in the assimilation of carbon, nitrogen, and the functions of nutrition, and whether they are beneficial or injurious, nothing whatever is known, although modern refinements in chemical methods have led to their frequent detection both in soil and in plants. That so important a problem

* Nuov. Giorn. Bot. Ital., xiv. (1882) pp. 147–55. Cf. this Journal, *ante*, p. 361.
† Journ. Franklin Institute, cxiv. (1882) pp. 41–9.

should have remained almost wholly unsolved must be attributed chiefly to the very great difficulties which are met in any experimental investigation, but also to the fact that the few investigations published have been carried out, in most cases, for the purpose of proving that vegetation had been injured by metallic compounds traceable to metallurgical works, and with the special purpose of founding a claim for damages, rather than to solve a scientific problem. The study of the influence of metallic compounds on plants has recently acquired great practical importance, from the fact that many manufacturing processes, more especially those employed in the smelting of lead and copper, and arsenical ores of various metals, have given rise to a gradual impregnation of the soil with such metals, and to the consequent poisoning of vegetation and animals.

The possibility of injury to plants has been denied on the assumption that they select such elements of the soil as are nutritious and reject all else.

Mr. Phillips has therefore undertaken experiments from which it seems safe to conclude : 1. That healthy plants grown under favourable conditions may absorb, through their roots, small quantities of lead, zinc, copper, and arsenic. 2. That lead and zinc may enter the tissues in this way without causing any disturbance in the growth, nutrition, and functions of the plant. 3. That the compounds of copper and arsenic exert a distinctly poisonous influence, tending, when present in larger quantity, to check the formation of roots, and either killing the plant or so far reducing its vitality as to interfere with nutrition and growth. In the case of the heavy metals, copper, zinc, arsenic, and lead, it seems to be probable that their oxides may under certain circumstances become deposited in the tissues of the plant. As to the manner in which this takes place, authorities differ.

It is supposed by Freytag and others, that plants absorb all soluble matters indiscriminately, through their numberless rootlets ; that the absorption of poisonous metals causes no disturbance until a certain degree of concentration is reached, when the plant rapidly withers and dies ; that plants are therefore spared the sufferings of chronic poisoning, but are very susceptible to acute poisoning, which is invariably fatal ; while it is held by others that plants absorb only such elements as are essential and nutritious, refusing to take up what is poisonous or innutritious ; metallic compounds found in the analyses are therefore to be traced to atmospheric deposit adhering externally. The theory of Freytag seems to the author to have the weight of facts in its favour, and if it is possible that crops may become charged in this way with poisonous elements of the soil, it becomes a matter of the highest importance that wherever there is danger of such impregnation the most efficient means be employed for its aversion ; for soil once impregnated with copper, lead, and zinc, may year after year bear crops poisoned in the same manner.

Decomposition of Calcium carbonate in the Stem of Dicotyledonous Woods.[*]—H. Molisch states that the deposition of calcium

[*] SB. K. Akad. Wiss. Wien, lxxxiv. (1881). See Bot. Centralbl., x. (1882) p. 161.

carbonate in the wood of dicotyledonous trees is not a rare pheno-
menon; but that it takes place only in the duramen or in parts of
the alburnum which resemble the duramen in properties. In knots
and wounded parts it is frequently separated in considerable quan-
tities. It is deposited especially in the vessels and tracheides, less
often in the libriform, parenchyma, and medullary rays. It occurs
abundantly in the pith when the wood that is in immediate proximity
to it assumes the nature of duramen, and becomes filled with lime.
An account is given of the different woods in which calcium carbonate
was found.

Hypochlorin.[*]—The investigations of Pringsheim [†] on the nature
and mode of formation of hypochlorin have been gone over by A. B.
Frank, with the following results:—

The hypochlorin reaction is found by Frank to bear the most
intimate relation to the presence of the colouring matter of chloro-
phyll; and this connection is the only constant one, there being no
relation to the presence or absence of conditions of assimilation.
Hypochlorin is never present in any other part of the protoplasm
than in that which is coloured by the chlorophyll-pigment, and here
it appears to be universal, whether the chlorophyll be in the form of
grains or spiral bands or in the amorphous condition. The hypo-
chlorin reaction manifests itself along with the very first trace of the
green colour in the young protoplasm, as was demonstrated in terminal
buds of *Elodea canadensis*, where the cells of the young minute leaves
are still in a merismatic condition, long before the differentiation of
the chlorophyll into grains, and when it is improbable that any
assimilation can take place. Hypochlorin is also found in the cell
till the close of the existence of the chlorophyll-pigment, in conditions
which exclude the possibility of assimilation.

The hypochlorin reaction is invariably accompanied by a destruc-
tion of the colouring matter of the chlorophyll. The first effects of
acids on chlorophyll-grains is a change of the green colour into
yellowish green or yellow, and this is followed by the separation of
oily drops of hypochlorin. If, however, the cells are killed, no
separation of hypochlorin takes place.

Two conditions are therefore necessary for the separation of
hypochlorin:—the living condition of the chlorophyll-grain, and the
presence of an acid. The reaction may be induced by hydrochloric,
sulphuric, nitric, phosphoric, acetic, lactic, tartaric, citric, picric, or
salicylic acid, and with very various degrees of concentration. The
cause of the change of colour of leaves in autumn is the disappearance
of the protoplasm from the cells, in consequence of which the chloro-
phyll-grains come into contact with the acid cell-sap. The same
changes take place when leaves become yellow from want of light.
The author believes that in this case the chlorophyll is not destroyed
directly by the want of light, but only by the secondary action of the
acid cell-sap in consequence of the destruction of the protoplasm.

[*] SB. Bot. Ver. Prov. Brandenburg, xxiii. (1822) pp. 11–16.
[†] See this Journal, iii. (1880) pp. 117, 480; i. (1881) p. 479.

In a different communication * J. Wiesner states his general concurrence with Frank's conclusion, which he would carry somewhat further. From its impermeability to organic acids, Wiesner regards protoplasm as having for one of its functions the protection of chlorophyll from injury from this source. The same process takes place also in fruits as in leaves.

Latex of Euphorbia Lathyris.†—An elaborate examination of the latex of *Euphorbia Lathyris* has led J. Schullerus to the conclusion that it must be regarded neither as a product of excretion (waste product) nor as a reserve material, but as a substance of actual direct service to the nutrition of the plant. The following are some of the special results at which he has arrived :—

The laticiferous tubes of this plant originate even in the embryo, and exclusively in the cells contiguous to the cortical parenchyma ; no laticiferous cells being formed at a later period or originating in any other way. They are found during the whole life of the plant, and in all its parts, in the root as well as the aerial portion. They may branch, but do not anastomose, either in the nodes or leaves. The growth of these tubes does not depend on that of contiguous cells, but is independent of them and may even be restricted by their growth ; they retain, during their existence, their power of apical growth and of branching at any spot. The latex of *E. Lathyris* is a formative sap, taking part directly in the processes of growth of the plant, and cannot be regarded as a mere reserve material. Its nutritive properties are proportionate to the amount of carbohydrate, especially starch, contained in it. When in an inactive condition it passes over to the state of a primordial latex. This is also the function of the latex of the permanent rhizomes of *Euphorbia palustris, orientalis, Pithyusa,* and *trigonocarpa,* rich in albuminoids, but containing but little carbohydrate. The absence of this property of storing up reserve materials distinguishes the laticiferous vessels physiologically from the cortical parenchyma. Besides osmotic movement, the latex possesses also a power of movement in mass, corresponding to the general movement of food-materials towards those parts where new formations are taking place, not due in any way to external influences.

These facts regarding the physiological function of the latex of *E. Lathyris* are true also for that of other species of *Euphorbia* which do not differ from it by any very strongly marked characters.

Darwin's so-called " Brain-function " of the Tips of Roots.‡— E. Detlefsen has investigated in a series of fresh experiments, the peculiar properties attributed by Darwin § to the extreme tips of

* Bot. Centralbl., x. (1882) pp. 260-6.
† SB. Bot. Ver. Prov. Brandenburg, xxiii. (1882) pp. 26-93.
‡ Arbeit. Bot. Inst. Würzburg, ii. (1882) pp. 627-47.
§ " It is hardly an exaggeration to say that the tip of the radicle thus endowed, and having the power of directing the movements of the adjoining parts, acts like the brain of one of the lower animals ; the brain being seated within the anterior end of the body, receiving impressions from the sense-organs, and directing the several movements."—Darwin, *The Power of Movement in Plants,* p. 573.

roots, and has come to the conclusion that his statement of these properties cannot in all respects be substantiated. He states that the curvatures manifested by the roots when a foreign body is applied to them on one side, and which Darwin attributes to the sensibility of the roots, are really due to injury suffered by the root from the cutting off of free access of air, all the tissues being found to be destroyed up to the cylinder of plerome. That the cause of the curvature is injury to the root-sap is shown by parallel experiments in which the injury is inflicted in other ways.

The statement of Darwin that it is only the apex of the root that is susceptible is also contested. Experiments with roots from which the tip had been entirely removed, showed the same geotropic phenomena as others in which the roots were entire.

The author further disputes Darwin's assertion that the apices alone of roots are susceptible to change in the degree of moisture of the environment; he states, on the contrary, that the whole of the growing part of the root, and not merely the tip, is affected by an unequal degree of moisture in the surrounding air, curving in the direction in which the air is most moist.

Aerial Cultivation of Aquatic Plants.*—E. Mer records the results of a series of experiments for the purpose of determining the effects produced by growing in the air plants which ordinarily grow entirely submerged in water. They were placed in a vessel of water in such a way that the buds were above the surface of the water, and the whole covered with a bell-glass; others being, at the same time, grown under similar vessels entirely in water. The sun, in July, was powerful during the whole of the experiments.

In *Potamogeton natans* and *rufescens* the shoots grown in the air were distinguished from the normal ones by the shortness of their internodes, the smallness of the leaves, which partially remained rudimentary, and the presence of numerous stomata, which were also found, but in small numbers, in the newly formed branches of the submerged specimens. The formation of stomata is ascribed by the author to the retardation of growth and to heredity. The accumulation of reserve-materials in the tissue resulting from the retardation may bring about divisions in the epidermal cells, and hence lead to the formation of stomata. The formation of stomata only in the parts exposed to air he attributes to more vigorous transpiration. Similar causes lead to the formation of stomata on the perianth-leaves of *P. rufescens* and the foliage-leaves of *Littorella lacustris*. Hereditary tendency causes the localization of the stomata on the upper side of the leaves in *P. natans*, as is usual in floating leaves; it also produces the effect in *Littorella* that, when grown in the air, the newly formed leaves possess a larger or smaller number of stomata, according as the plants grew originally at a greater or less depth below the surface of the water.

In *Hydrocharis morsus-ranœ* the size of the leaves was greatly diminished, as well as the length of the leaf-stalk, the intercellular

* Comptes Rendus, xciv. (1882) pp. 175-8.

spaces and epidermal cells were smaller, and the latter had somewhat wavy outlines. In *Nuphar pumilum* the leaves were smaller and contained less starch.

The author concludes that the incapacity of certain water plants to produce branches outside the water depends on their inability to resist strong transpiration, and not on any incapacity to grow and nourish themselves in the air. They thrive in the air if it is only sufficiently moist to reduce transpiration to a small amount.

Insectivorous Plants.*—A. F. W. Schimper gives detailed descriptions of several insectivorous plants, natives of North America. In the first place, the structure is more fully described than heretofore of the asciform leaves of *Sarracenia purpurea*. It was clearly determined that the products of decomposition of the insects and other organic substances found in the pitchers enter the cells of the leaf, as is shown by the changes which take place in the protoplasm of the cells thus affected. In these cells Schimper noticed a phenomenon closely resembling that described by Darwin as occurring in *Drosera* under the name " aggregation of protoplasm." In fact, however, in *Sarracenia*, the aggregations consist of a concentrated solution of tannin, which substance is always present in the cell-sap.

There occur in North America three species of *Utricularia*, land-plants growing in moist sandy situations. Of these *U. cornuta* was especially examined, and presents several very singular points of structure. The plant possesses no true root, the rhizome branching into several root-like organs, which bear the bladders in great quantities, and which the author believes to be homologous to the floating leaves of the aquatic species. The bladders are similar in form to those of *U. vulgaris*, but want the "antennæ," as is also their histological structure, which is described in detail. They contain, besides inorganic bodies, small animals and Algæ, especially diatoms, rotifers, and crustacea; the animals were never found alive, but usually much swollen and decomposed, and this was also the case with the diatoms, the contents of the bladders being apparently poisonous to both animals and plants. The hairs of the bladders appear to act as organs of absorption; and in the contents of their cells similar changes were observed to those described in the cases of *Sarracenia* and *Drosera*. As in *Dionæa*, an excess of nutriment is injurious to the plant.

Climbing Plants.†—In opposition to the view of Von Mohl, S. Schwendener denies the existence of a special faculty of irritability to which the twining of climbing stems and tendrils is due. He considers all the phenomena of these organs to be explicable by the laws of circumnutation and of geotropism.

Power of Movement in Plants.‡—In J. Wiesner's work on this subject he goes through the results published by Darwin in his work

* Bot. Ztg., xl. (1882) pp. 225–34, 241–8 (1 pl.).
† SB. Bot. Ver. Prov. Brandenburg, xxiii. (1882) pp. 9–11.
‡ Wiesner, J., 'Das Bewegungsvermögen der Pflanzen,' 212 pp., Vienna, 1881. See Bot. Ztg., xl. (1882) pp. 202–8. See also 'Nature,' xxv. (1882) pp. 578–82; 597–601.

bearing the same title, and in a great many points comes to a more or less different conclusion, his arguments being in all cases founded on actual experiments. The following are some of the more important points in which he differs from Darwin.

As regards circumnutation, Wiesner doubts its existence in roots, attributing this apparent phenomenon to the antagonism between geotropism and the natural tendency to curvature existing in roots, first one and then the other of these forces getting the upper hand, and thus moving the tip of the root backwards and forwards. In the case of stems, also, he considers that there are some plants which do not exhibit circumnutation. Some leaves also, he states, grow in absolutely straight lines without circumnutating, the apparent circumnutation being here again due to the varying action of opposing forces, viz. epinasty, apogeotropism, apheliotropism, and gravitation.

Wiesner's explanation of heliotropism agrees with that of De Candolle, that the convex side grows more quickly simply because it is in shade.

The author disputes the value of Darwin's experiments which are alleged to prove the sensitiveness of the tips of radicles, attributing the observed phenomena to injury resulting from the means employed.

Electrical Researches on Plant Forms.*—The absorption of water by porous bodies is accompanied by electric currents. When a porous earthenware cell is partly filled with water, and a current completed through a galvanometer by means of electrodes in the water and in contact with the outer wall of the cell, a current passes. The intensity continually diminishes, until it finally ceases, and then a current begins in the opposite direction from the cell-wall through the water. This reversal of current is due to the incomplete state of saturation of the walls of the cell. These phenomena are employed by A. J. Kunkel to account for various electric phenomena observed in plants.

In regard to the electromotive action of the upper surface of green leaves, the difference of tension of the various parts was determined by a systematic method of contact over the whole surface, with the result that the leaf-veins are generally positive towards the rest of the leaf, but the direction of the current is reversed if the spot on the leaf where the electrode is placed is wetted before the other electrode is placed on the vein. Also a spot long moistened is positive towards one freshly wetted. When the electrodes rest on the epidermis of a plant and a wound is made near the electrode, then that electrode will be negative to the other. The same result is obtained by bending the plant, and the current formed is the more intense the greater the amount of bending, the electrode near the bend being negative to the other. Sometimes plants also show the existence of electric currents, which when the plant moves cause the galvanometer needle to oscillate.

* Bied. Centr., 1882, pp. 28–30. Cf. Journ. Chem. Soc. Abstr., xlii. (1882) p. 638.

Electromotive Properties of the Leaf of Dionæa.[*]—Professor J. Burdon Sanderson has investigated the immediate and subsequent electrical results of excitation of the leaf of *Dionœa*, which have previously been examined by Munk, Kunkel, and the author himself.

It is found that at the moment of excitation (whether mechanical or electrical) the under surface of the lobe of the leaf is electro-negative to the upper surface, the difference of potential reaching its maximum about half a second after excitation ; it then rapidly decreases until the upper surface is ultimately electro-negative to the lower, and this after-effect remains constant for some time.   With a current not much more than adequate, excitation occurs at the moment of closing the current, but none occurs on breaking the circuit unless the current be sufficiently strong.   The author considers (1) that the difference of potential is due to the electromotive forces which reside in the living protoplasm of parenchyma-cells in contact with one another, and in different states of physiological activity ; (2) that the second phase of excitation is probably dependent on the diminution of turgescence of the excited cells, arising from a migration of liquid ; (3) this explanation cannot be accepted for the phenomena of the first phase, the sudden accession and rapid propagation of which show that it is probably analogous to the " negative variation " or " action current " of animal physiology.

Influence of a Galvanic Current on Growing Roots.[†]—F. Elfving has observed the effect of a continuous current of electricity upon the growing organs of plants, especially roots, and finds that it causes a distinct curvature of the organ in the direction of the positive pole. This curvature has not, however, any physiological significance, like those due to geotropism and heliotropism ; it is due to the retarding effect on growth of the current of electricity, especially on that side of the organ which the current meets directly.

B. CRYPTOGAMIA.

Cryptogamia Vascularia.

Schizæaceæ.[‡]—The second part of Prantl's work on the Vascular Cryptogams is devoted to this group of ferns, and especially to the morphology of the non-sexual generation.

The first section is occupied with the arrangement of the leaves on the stem and the structure of the leaves and stem.   There occur both radial and dorsiventral stems, the most remarkable among the latter being *Lygodium*, which has a single dorsal row of leaves, this arrangement originating even in the growing point.   A similar structure occurs also in other ferns.

The genus *Lygodium* is also of special interest with respect to the structure of the sporangia.   Each sporangium is here enclosed in a pocket, the upper wall of which is composed of the surface of the leaf

---

[*] Proc. Roy. Soc., xxxiii. (1882) pp. 148–51.

[†] Bot. Ztg., xl. (1882) pp. 257–64 ; 273–8.

[‡] Prantl, K., ' Unters. zur Morphologie der Gefässkryptogamen.   Heft ii. Die Schizæaceen.'   Leipzig, 1881.

itself, while the lower wall is a lamella of tissue springing from the outer part of a vein.   The sporangium springs, as in *Anemia*, from the margin of the leaf, while behind the sporangium is formed an annular wall, the indusium, which encloses the sporangium like a hood, the sporangium becoming eventually placed, in the course of development, on the under side of the leaf.   Such a sporangium, covered by an indusium, is termed by the author a " monangic " sorus.

The apex of the young leaves is occupied by a wedge-shaped apical cell.   In the finer veins the structure of the vascular bundles is collateral.   No spiral vessels occur in the stem, and the sieve-tubes are very small.   The mesophyll does not possess any true palisade-parenchyma, and is very nearly alike on the two sides of the leaf.   The epidermis is not sharply separated from the fundamental tissue.   In *Anemia* and *Schizœa* the cuticle is provided with siliceous warts.   In *Anemia elegans* the stomata occur only on the upper side of the leaf. Those of *Schizœa* are arranged in two longitudinal rows on each side of the veins.

As regards classification, Prantl divides the Filices into three primary groups, viz. (1) Hymenophyllaceæ, Polypodiaceæ, and Cyatheaceæ ; (2) Schizæaceæ, Gleicheniaceæ, and Parkeriaceæ ; and (3) Osmundaceæ, Ophioglossaceæ, and Marattiaceæ.   *Ceratopteris* he treats as belonging to the Schizæaceæ ; it has monangic sori, as also has *Botrychium*.   The author regards the Schizæaceæ as presenting the closest affinity among ferns to flowering plants.   He inclines to the view that the nucellus of the ovule is homologous to the sporangium, and the entire ovule to a monangic sorus with its indusium.

Muscineæ.

Branched Sporogonium of a Moss.*—C. Fehlner describes an instance of branched sporogonium in *Meesea uliginosa*.   From a common seta spring two sporangia, each with normal operculum and peristome.   The capsule of *Meesea* not being regular, but laterally symmetrical owing to a curvature, the two sporangia are placed back to back in the same plane of symmetry, and the mutual pressure causes the surfaces which are in contact with one another to be somewhat flattened.

Leitgeb regards this and similar recorded cases of branched sporogonium as indicating reversion towards earlier forms of Archegoniatæ in which the sporogenous generation is normally branched.   He states that they do not result from the archegonium containing two oospheres, or from coalescence of two embryos, but from vertical segmentation of the apical cell of the embryo, which therefore branches when it has attained a certain stage of development.

Influence of Light on the Thallus of Marchantia.†— A. Zimmermann contests Pfeffer's statement that the development of root-hairs from the gemmæ of *Marchantia* is determined only by contact with the surface of the soil ; he finds, on the contrary, that in addition

---

* Oesterr. Bot. Zeitschr., xxxii. (1882) p. 185.
† Arbeit. Bot. Inst. Würzburg, ii. (1882) pp. 665-9.

to this contact and to gravitation, the absence of light is also a factor in determining on which side of the thallus the root-hairs shall be produced. Precisely the same results were obtained with gemmæ of *Lunularia*. The author confirms, on the other hand, the assertion of Pfeffer that the organic upper side of the thallus of *Marchantia* is always the side which faces the light. This was determined by cultivating the thallus both of *Marchantia* and *Lunularia* on the surface of water. He considers these observations to have an important bearing on those of Leitgeb and Prantl * on the bilateralness of the prothallium of ferns.

Goebel's Muscineæ.†—In his most recent account of the Muscineæ, Dr. K. Goebel introduces no fresh element into the main principle of their classification. The Hepaticæ are divided into two main groups, the Marchantiaceæ (subdivided into the Riccieæ, Corsinieæ, and Marchantieæ) and the Jungermanniaceæ (Jungermannieæ and Anthocoroteæ). In the Musci he groups the Sphagnaceæ and Andreaceæ together as one type, the Phascaceæ and Bryineæ together as a second type. In each group the various organs are treated in succession :—Firstly, the vegetative organs and the non-sexual mode of reproduction ; then the sexual organs, and the development and structure of the second generation, ending with the structure and germination of the spores. A new instance of vegetative budding is described from the calyptra.

In their genetic relationship, Goebel regards the Hepaticæ and Musci as two offshoots from the same stem, the lowest Hepaticæ presenting the nearest resemblance to the original stock. They may possibly have sprung from the Thallophytes through *Coleochæte*, the hibernating oospore of which presents no great diversity from the sporogonium of *Riccia*. In the ascending scale the Muscineæ have no derivative forms, the series ending with them.

Characeæ.

Development of the Cortex in Chara.‡—T. F. Allen employs the mode of development of the cortex as a new basis for the classification of the species of *Chara*, and distinguishes the following eight methods :—

1. Some species never develope cortex-tubes, and the stems remain naked (*C. coronata* Ziz.).

2. Some species develope a single cortex-tube, which is so small that it does not join the one from the next leaf (*C. inconnexa* Allen).

3. Some cortex-nodes develope spines, but no secondary tubes ; the primary tubes join and completely encircle the stem (*C. crinita* Wallr.).

4. Some cortex-tubes show a partial development of secondary tubes (*C. evoluta* Allen).

* See this Journal, ii. (1879) p. 917 ; iii. (1880) p. 121.
† Goebel, K., 'Die Muscineæ.' Encyklopædie der Naturwissenschaften, 1te Abtheil. 28 Lief. pp. 315-401.
‡ Bull. Torrey Bot. Club, ix. (1882) pp. 37-47 (8 pl.).

5. Some cortex-tubes develope one secondary cell only, which becomes as long as the primary cell, but is of smaller diameter (*C. excelsa* Allen, *C. intermedia* A. Br., *C. contraria* A. Br. Sect. Tylacanthæ).

6. Some develope only one lateral cortex-cell, which becomes larger than the primary cell and partially covers it, so that the primary cell seems to lie in a furrow (*C. fœtida* A. Br. Sect. Aulacanthæ).

7. Some cortex-cells develope perfectly one lateral cell, and imperfectly another (*C. aspera* Willd.).

8. Some cortex-cells develope perfectly both lateral cells, so that three complete series of cells arise from each leaf (*C. fragilis* Desv., *C. gymnopus* A. Br.).

Details of the application of these characters are followed by full descriptions of the following new American species:—*C. inconnexa, evoluta,* and *excelsa.*

Fungi.

Ustilagineæ.[*]—The fifth part of De Bary and Woronin's 'Morphology and Physiology of Fungi' is occupied by a treatise on the Ustilagineæ by M. Woronin.

The first section consists of a complete life-history of *Tuburcinia Trientalis* Berk. and Br., which attacks the stem, leaves, and rhizome of *Trientalis europæa*. The mycelium consists of sparingly septated and irregularly branched hyphæ which permeate the intercellular spaces, and put out haustorial lateral branches into the cells themselves of the host; these branches, with their short irregular secondary branches, having somewhat the form of a bunch of grapes. On this mycelium are produced two kinds of reproductive organ, conidia and resting-spores. The conidia are always borne on the under side of the leaves of the host, and form a white mould-like coating, the *Ascomyces Trientalis* of Berk. The hyphæ on which they are borne form a more or less dense felt between the epidermis and the mesophyll; lateral branches then penetrate through the stomata or between the walls of the epidermal cells, and bear the pear-shaped conidia, either first putting out haustoria or not. The conidia germinate readily in water, putting out a germinating filament, which either at once developes a conidiophore, or continues to grow without putting out conidia. Conidial hyphæ are also produced by sowing conidia on moistened leaves of *Trientalis*. These give rise to small patches of mycelium, on which the resting-spores are developed.

The resting-spores form brown *Sorosporium*-like masses, dusky patches $\frac{1}{2}$–2 mm. in diameter, on the leaves and leaf-stalk of the host. These spores are produced on much-branched mycelial filaments, which appear usually to be of smaller diameter than the purely vegetative ones, to be more freely septated, and usually destitute of haustoria. In their youngest stage they have the form of straight or curved, spiral or twisted branches, either singly or in coalescent

pairs. These become septated, and some or all of the cells become vesicular. Soon a number of these hyphæ amalgamate into a dense ball, the vesicular cells at the same time increasing in size. In this way is formed a fructification, the interior of which is composed of the spores, polyhedral cells with ultimately thick and brown walls, comparatively large and numerous (as many as 100). The filamentous envelope of hyphæ ultimately gelatinizes and disappears. The process agrees in essential points with that in *Sorosporium Saponariæ.* The resting-spores do not remain dormant through the winter, but germinate late in the autumn of the same year on the host, each of the spores germinating separately. The process corresponds to that in *Tilletia*, each spore putting out a promycelium, which forms at its apex a cluster of cylindrical-fusiform sporidia in groups of from four to eight. While they are being formed the protoplasm leaves the basal part of the promycelium, and becomes separated by a septum from the empty portion, the promycelium thus becoming bicellular. The sporidia are abstricted from the terminal cell, which Woronin calls the basidial cell, and compares with the basidium of the Basidiomycetes. Unlike *Tilletia*, it becomes completely detached from the other cells. Two sporidia frequently anastomose, a process which Woronin regards as one of conjugation. One of the conjugating sporidia developes at its apex a secondary fusiform sporidium ; but this also takes place in those which do not conjugate. They may even produce tertiary sporidia. After the sporidia have become detached, the basal cell, if still containing protoplasm, may put out a germinating tube. The sporidia and conidia bear no resemblance to one another in form. The sporidia are carried to the ground by rain or dew, and in this form again reach the leaves or stem of the host, which they penetrate with their mycelia.

In the second section, the author describes the mode of germination of the spores of other species of Ustilagineæ, which frequently differs in minor points from that of *Tuburcinia*, viz. :—*Sorosporium Saponariæ, Tolyposporium Junci, Thecaphora hyalina, Entyloma Aschersonii, E. Magnusii*, and *Melanotænium endogenum.*

In the third section these results are compared, and the group classified according to the mode of germination, as follows :—

I. No sporidia are formed in germination.

a. The spores put out long and copiously septated germinating filaments, which either are unbranched or the upper protoplasmic cell puts out lateral irregularly distributed branches. The terminal cell sometimes becomes detached, and carries on an independent existence—*Sorosporium.*

b. The growth of the germinating filaments is limited, and they form a promycelium. They are septated, but instead of producing sporidia, put out filaments, which usually grow in opposite directions, and which conjugate at their apices, then developing the true germinating filament—*Thecaphora.*

II. The promycelium is septated into a number of cells, from each of which is abstricted one or more sporidia :—*Ustilago-Schizonella* (*S. melogramma* DC.), *Tolyposporium.*

III. At the apex of the promycelium is formed a whorl of from two to eight usually fusiform branches, also termed sporidia, which usually conjugate in pairs, developing finally into secondary sporidia or directly into long, slender, simple or branched germinating filaments : — *Tilletia, Entyloma, Melanotœnium, Schroeteria, Urocystis, Tuburcinia.*

The following species, nearly allied to *Tuburcinia,* are also specially described :—*Thecaphora aterrima* Tul., *Sorosporium schizocaulon* Ces., *S. Müllerianum* Thüm., *Urocystis Paridis* Thüm. (*Sorosporium Paridis* Wint., *Polycystis opaca* Strauss, *Urocystis Colchici* f. *Paridis* F. v. Waldh.), *Tuburcinia Veronicæ* Schröt., *T. Cesati* Sor., *T. scabies* Berk.

Unobserved Sensitiveness in Phycomyces.*—F. Elfving has observed that if a moist disk of gypsum is brought near to growing *Phycomyces,* the sporangiophores will lose their upright growth and bend in various directions ; and this will take place even if the atmosphere is saturated with aqueous vapour. The author suggests that the phenomenon is due to contact electricity.

Beltrania, a New Genus of Hyphomycetes.†—Under the name *Beltrania rhombica* O. Penzig describes a hyphomycetous fungus constituting a new generic type, found on the under side of fallen lemon leaves in Sicily, on which it forms an olive-coloured velvety coating. It presents most affinity to *Fusicladium* and *Scolecotrichum,* but differs from them in having sterile filaments in addition to the sterigmata, and the bicellular beaked spores collected in clusters on short basidia. The following is the technical description of the genus :—

Cæspitulis hypophyllis, stratum fusco-olivaceum constituentibus ; hyphis erectis vel adscendentibus, dense aggregatis, continuis vel 1–2-septatis, subsimplicibus, sinuosis ; setulis sterilibus longioribus inter hyphas fertiles intermixtis ; conidiis vel in hypharum apice sessilibus vel sterigmate ex apice oriundo suffultis, solitariis vel fasciculatis, 1-septatis, apice rostratis.

Chemical Composition of Moulds.‡—N. Sieber has prepared a growth of pure *Aspergillus, Mucor,* and *Penicillium,* the absence of Schizomycetes being assured by the presence of free phosphoric acid in the nutrient fluid. An analysis of the alcohol and ether extract, of which the exact composition is given, showed that it consisted entirely of albumen and cellulose. Further experiments show that the form of albuminoid present was not that of mycoprotein. A very small quantity of an undetermined substance crystallized out of the extract.

Salmon Disease.§—Professor T. H. Huxley, in his observations on this disease, not only examined the minute structure of both the healthy and diseased skin, but also tried some experiments on the

transplantation of the *Saprolegnia* of the living salmon to dead animal bodies.

The body of a recently killed common house-fly was gently rubbed two or three times over the surface of a patch of the diseased skin of a salmon, and was then placed in a vessel of water, on the surface of which it floated, in consequence of the large quantity of air which a fly's body contains. In the course of forty-eight hours, or thereabouts, innumerable white cottony filaments made their appearance, set close side by side, and radiated from the body of the fly in all directions. As these filaments had approximately the same length, the fly's body thus became enclosed in a thick white spheroidal shroud, having a diameter of as much as half an inch. As the filaments are specifically heavier than water, they gradually overcome the buoyancy of the air contained in the tracheæ of the fly, and the whole mass sinks to the bottom of the vessel. The filaments are very short when they are first discernible, and usually make their appearance where the integument of the fly is softest, as between the head and thorax, upon the proboscis, and between the rings of the abdomen. These filaments, in their size, structure, and the manner in which they give rise to zoo-sporangia and zoospores, are precisely similar to the hyphæ of the salmon fungus; and the characters of the one, as of the other, prove that the fungus is a *Saprolegnia* and not an *Achlya*. Moreover, it is easy to obtain evidence that the body of the fly has become infected by spores swept off by its surface when it was rubbed over the diseased skin. These spores have in fact germinated, and their hyphæ have perforated the cuticle of the fly, notwithstanding its comparative density, and have then ramified outwards and inwards, growing at the expense of the nourishment supplied by the tissues of the fly.

This experiment, which has been repeated with all needful checks, proves that the pathogenic *Saprolegnia* of the living salmon may become an ordinary saprogenic *Saprolegnia*; and, *per contra*, that the latter may give rise to the former, and they lead to the important practical conclusion that the cause of salmon disease may exist in all waters in which dead insects, infested with *Saprolegnia*, are met with; that is to say, probably in all the fresh waters of these islands, at one time or another.

On the other hand, *Saprolegnia* has never been observed on decaying bodies in salt water, and there is every reason to believe that as a saprophyte, it is confined to fresh waters.

Thus it becomes, to say the least, a highly probable conclusion that we must look for the origin of the disease to the *Saprolegniæ* which infest dead organic bodies in our fresh waters. Neither pollution, drought, nor overstocking will produce the disease if the *Saprolegnia* is absent. The most these conditions can do is to favour the development or the diffusion of the *materies morbi* where the *Saprolegnia* already exists.

The results of the last season's observations on the salmon disease appear to justify the following conclusions :—

1. That the *Saprolegnia* attacks the healthy living salmon exactly

in the same way as it attacks the dead insect, and that it is the sole cause of the disease, whatever circumstances may, in a secondary manner, assist its operations.

2. That death may result without any other organ than the skin being attacked, and that, under these circumstances, it is the consequence partly of the exhaustion of nervous energy by the incessant irritation of the felted mycelium with its charge of fine sand, and partly of the drain of nutriment directly and indirectly caused by the fungus.

3. That the penetration of the hyphæ of the *Saprolegnia* into the derma renders it at least possible that the disease may break out in a fresh-run salmon without re-infection.

4. That the cause of the disease, the *Saprolegnia*, may flourish in any fresh water, in the absence of salmon, as a saprophyte upon dead insects and other animals.

5. That the chances of infection for a healthy fish entering a river are prodigiously increased by the existence of diseased fish in that river, inasmuch as the bulk of *Saprolegnia* on a few diseased fish vastly exceeds that which would exist without them.

6. That as in the case of the potato disease, the careful extirpation of every diseased individual is the treatment theoretically indicated, though, in practice, it may not be worth while to adopt that treatment.

Formation of Saccharomyces in Nutrient Fluids containing various Proportions of Nitrogen.[*]—M. Hayduck finds asparagin especially well adapted as a source of nitrogen for *Saccharomyces*. The mineral ingredients of the nutrient fluid were a mixture of 50 g. acid potassium phosphate, PH_2KO_4 and 17 g. crystallized magnesium sulphate; and the following results were obtained :—

1. The nitrogen contained in a nutrient fluid is assimilated by the yeast only up to a certain degree of concentration ; and above this limit the nitrogen is not used in the production of yeast. (2) In all the experiments an excretion of nitrogen was observed. (3) When formed in very dilute solutions the yeast contains a constant minimum proportion of nitrogen ; as the proportion of nitrogen in the solution increases, the amount of yeast formed remains the same, while the proportion of nitrogen in it increases. But beyond a certain limit, the amount of nitrogen in the fluid increases neither the amount of yeast produced nor the proportion of nitrogen in it. (4) The fermenting power of the yeast depends partly on the proportion of nitrogen contained in it. (5) Yeast containing a large amount of nitrogen can increase in a pure solution of sugar, a portion of the nitrogenous contents of the mother-cells being used in the formation of the daughter-cells. (6) The growth of the yeast may be affected by the formation of one or more products of fermentation, alcohol especially exerting a prejudicial influence upon it.

[*] Zeitschr. f. Spiritusindustrie, 1881, p. 173. See Bot. Centralbl., x. (1882) p. 153.

Morphology and Genetic Relationship of Pathogenous Bacteria.[*] —Dr. T. Haberkorn thus sums up the results of a series of observations on this subject:—(1) The four tribes of Cohn, spherobacteria, microbacteria, desmobacteria, and spirobacteria, cannot be maintained; these being all forms of a single genus with numerous species. (2) The history of development of the bacteria of malaria, typhus, and acute contagium is essentially the same, including pleomorphy and a definite alternation of generations. (3) Each of these diseases is accompanied by a distinct species of bacterium; typhoid having also one of its own. (4) The various species of bacteria are distinguished by their conditions of existence, size, colour, habit, movements, and metastasis.

Pathogenous Bacteria.[†]—V. Babes has convinced himself that there are no bacteria in the blood or the tissues of healthy men; this judgment is based on the personal examination of more than one hundred bodies. He once observed the growth of filaments of *Bacillus anthracis* from spores in the sexual organs of a woman. Bacterian colonies, and not rods only, were observed in a case of *Anthrax intestinalis;* other examples of similar phenomena were observed, and weaken the generally accepted doctrine that rods alone are found in the living body. The author has for a long time used aniline green and aniline violet as colouring agents.

Bacterium of Charbon.[‡]—The temperature which seems most favourable to the bacterium of *charbon,* is that of mammalia (37° C.). Birds, having a higher temperature (about 42°), do not take the disease under ordinary conditions. Pasteur, however, has developed it in fowls by lowering the temperature (keeping the feet in cold water).

M. Gibier has now experimented with frogs, and finds that they do not suffer after inoculation in the normal state; but if kept, after being inoculated, in water at about 37°, they may take the disease (five out of twenty did—most of the others died soon after immersion). The bacteria developed were remarkable for their great length, and this is attributed to the slowness of the circulation.

Connection of Bacteria with Ferments.[§]—J. Rossbach finds that the death which ensues in one to two hours after the injection of papayotin into the rabbit is accompanied by the appearance of large quantities of bacteria in the blood. These were ascertained to be entirely absent before the injection; but introduction of as small quantities as 0·05 to 0·1 gramme of this substance resulted, after death, in the presence of a large number of moving globular and "hour-glass-shaped" bacteria in every drop of blood taken from the heart. Thus it appears that the presence of a small quantity of an unorganized and purely chemical substance is sufficient to produce in the body conditions which induce the rapid multiplication of microphytes already existing there in insignificant quantities. This

supports the view that chemical poisons or ferments play an important part in the injections connected with organic germs.

Lichenes.

Life-history of Cora.[*]—The genus *Cora*, established by Fries, has been regarded by some as belonging to Algæ, by others as belonging to Fungi, while Nylander, who detected the true fructification as consisting of apothecia and ascospores, maintained it to be a lichen. O. Mattirolo has carefully examined all the known species, and fully confirms Nylander's view.

In the thallus is a well-defined gonimic layer, the gonidia belonging to the genus *Chroococcus*. One species, *Cora ligulata* Kremp., must be erected into a distinct genus in which the gonidia have a *Scytonema*-form; Mattirolo proposes for it the name *Rhipido-nema*. The author has not been able to confirm Nylander's account of the occurrence of apothecia, which probably belonged to a different lichen or fungus. Both *Cora* and *Rhipidonema* have on the under side a true hymenium, something like *Thelephora* or *Kneiffia*, formed of basidia which are the apices of special hyphæ. Each basidium bears a sterigma, on which is a single spherical spore, as in *Kneiffia*.

The author holds, therefore, that we have in these two genera lichens in the building up of which Basidiomycetes, and not Ascomycetes, have taken part. This new group he terms HYMENOLICHENES, and places them among the Basidiomycetes, near to *Kneiffia, Corticium, Stereum, Thelephora,* and *Hypochnus.* It includes the following species :—*Cora Pavonia, glabrata, gyrolophia,* and *Neesiana,* and *Rhipidonema ligulata.* They are all extra-European, and abundant in the tropics.

Minks's Licheno-mycological Symbols.[†]—In his last essay on the structure and affinity of lichens, Dr. A. Minks recapitulates the grounds of his microgonidial theory,[‡] and recommends *Leptogium myochroum* as a specially favourable species for establishing the existence of microgonidia. The ascus of a lichen he regards as simply a highly differentiated hypha, the terminal cell of which has the power of dividing so as to produce the spores. Neither in the history of their development nor in their structure do the spores correspond to the ascospores of the true Ascomycetes; and their mode of germination is also different.

The portion already published of Dr. Minks's work includes descriptions of 170 species; and the whole family is intended to be gone through at the rate of about 200 species per annum.

Algæ.

Symbiosis of Algæ with Lower Animals.[§]—Since so many naturalists have published observations on this subject, Dr. G. Entz

---

takes occasion to call attention to some results of his own, published in Hungarian in 1876. From a study of the chlorophyll-bodies of Infusoria, he had come to the conclusion that their presence there was not distinctive of any special group of Infusoria. These bodies only occurred in omnivorous species; and those species in whom they occurred in abundance were noticed to take in no solid food, but only to agitate water in their œsophagus. He characterized these green bodies as Algæ, and stated their relation to their hosts as being a perpetual source of nutriment to the latter, which in their turn furnish them with a safe domicile; the Infusorian supplies the alga with carbonic acid, while the alga produces oxygen for its host. "We have thus to do in this case with a fellowship or peculiar consort relation between two totally different organisms, which may be compared in some respects to the organization of the lichens, which, according to Schwendener's interpretation, owe their existence to the association of a fungus with an alga." Entz has subsequently continued his study of this question, and has been able clearly to see a nucleus in these chlorophyll-bodies, and to determine that the mass is generally invested by a hyaline gelatinous envelope, and thus exhibits all the characteristics of the *Palmellaceæ*. He finds that the zoospores of various low Algæ and green Flagellates as well may become converted into these "pseudo-chlorophyll-bodies."

Division of the Cell-nucleus in Spirogyra.[*]—E. Tangl gives the following results of observations on an undetermined species of *Spirogyra* :—

1. The membrane of the cell-nucleus, when at rest, has a reticulate structure; but the author was unable to determine whether this was the result of local differences in density, or of actual perforation.

2. The nucleus contains, as a rule, only a single nucleolus, and includes, when at rest, besides the nucleolus, a finely granular mass, very poor in substance, and only slightly tinted by colouring reagents; the nucleolus is bounded by a membrane which is not tinted.

3. The nuclear spindle, the formation of which is preceded by demonstrable changes in the contents, is of the type described by Strasburger, and consists of equatorial rod-like elements which are not separated.

4. The portion of the original contents present in the "spindle-stage" of the nucleus, and only slightly tinted by reagents, is subsequently resorbed during the formation of the daughter-nuclei.

5. These facts appear to corroborate Strasburger's view that the spindle-fibres are derived from the protoplasm which is forced into the nucleus.

6. During the separation of the two halves of the nuclear plate a uniting tube is formed, proceeding from the membrane of the nucleus which is already perforated at the two poles at the "spindle-

stage," and the enveloping membrane of the nucleolus, the inner surface of which is closely applied to the uniting threads.

7. This combining tube constitutes the lining of an internal cavity of the mother-cell, which is relatively very large at a certain stage of the division, and which is closed outwardly by the rudiments of the daughter-nuclei. The further behaviour of this tube corresponds to that of the uniting threads in the species described by Strasburger.

Batrachospermum.*—G. Arcangeli describes in detail several species of *Batrachospermum*, among them one new one, *B. Julianum*, found in thermal waters near Pisa. He describes the genus as presenting, in the same species, two modes of multiplication of cells, by segmentation and by gemmation. The former occurs in the terminal cell of the stem and of the primary branches, and is the mode by which these organs lengthen, also in the cortical branches; while the verticillate branches are formed and lengthen by gemmation. At a short distance from the terminal cell of the stem and of the primary branches, the rudiments of the verticillate branches make their appearance in the form of hemispherical protuberances, which separate themselves from the mother-cell by means of a tangential septum. *B. Julianum* differs from the other species in the mode of development of the female organ, presenting a considerable resemblance to that in *Nemalion;* and the author considers that it establishes an intimate relation between the mode of fertilization in *Batrachospermum* and in the Florideæ. Although the thermal water in which *B. Julianum* grows, produces also a species of *Chantransia*, he was unable to detect any genetic connection between these genera, as stated by Sirodot.

New Beggiatoa.†—A. Engler has observed the barren salt ground in the neighbourhood of the harbour at Kiel to be densely covered with the dusky white filaments of several species of *Beggiatoa*, especially *B. alba* Vauch. var. *marina* Cohn (*B. Œrstedii* Rabenh.). Attached to the legs of crabs in the deep water of the same harbour he finds a new species, not corresponding completely to any hitherto described, which he calls *Beggiatoa multiseptata*. Associated with it is another form, resembling *Cladothrix*, but not belonging to the Schizomycetes, which Engler regards as the type of a new genus, and names *Cladomyces Mœbiusii*. It must be placed near *Stigeoclonium*.

Vampyrella.‡—J. Klein attempts to answer the question whether this organism is animal or vegetable, and has for this purpose examined four species, three of them new, *Vampyrella variabilis*, *inermis*, and *pedata*. In the resting condition *Vampyrella* forms, according to the species, stalked or sessile capsules, attached to various fresh-water Algæ.

A more exact description is given of *V. variabilis*, which occurs in

---

* Nuov. Giorn. Bot. Ital., xiv. (1882) pp. 155–67 (2 pls.).
† SB. Bot. Ver. Prov. Brandenburg, xxiii. (1882) pp. 17–20.
‡ Bot. Ztg., xl. (1882) pp. 193–200, 209–17 (1 pl.).

the form of globular, ellipsoidal, or irregular cysts in the empty cells of fresh-water confervæ. When ripe the contents are reddish, orange-yellow, or bright red, including a dark spot. The endochrome subsequently escapes in two, four, or more masses, which, as they gradually escape from the cyst, are clothed at the edge with a fringe of cilia, the dark body remaining still enclosed within them. The escaped ciliated bodies must be regarded as zoospores, and are provided with pseudopodia, moving about slowly with an amœboid motion. When two meet, and their pseudopodia come into contact, they slowly coalesce, and this the author regards as a kind of conjugation. The resulting bodies appear to be of the nature of plasmodia, are endowed with a creeping motion, and may again coalesce. These larger bodies attach themselves to certain algæ, ultimately become encysted, and then again go through the same course of development. Those zoospores which do not conjugate also become eventually encysted. Attached to the conferva are also found cysts of the *Vampyrella* of a different kind, resting cysts which remain for a time in a dormant condition before any further development takes place.

Vampyrella pendula and *inermis* agree with *V. variabilis* in essential characters, while *V. pedata* differs in some important points, and may, perhaps, be the type of a distinct genus. It is found, like the two last species, attached to *Œdogonium;* its zoospores have neither cilia nor pseudopodia, but a long projecting colourless beak, which is in front during the motion of the body, and appears to guide its movement by bending in different directions, finally becoming encysted, apparently without conjugation. These bodies have been described by zoologists as rhizopods (*Hyalodiscus rubicundus* Hertwig and Lesser, and *Plakopus ruber* F. E. Schulze).

A full description follows of seven distinct species of the genus ; and the author concludes, taking all the points of structure into consideration, that *Vampyrella* is most nearly allied to the Chytridiaceæ and Myxomycetes, and must be regarded as a plant ; but that it exhibits in some respects a transitional character to the animal kingdom.

Schizophyceæ.*—W. Zopf has undertaken a fresh examination of the lowest forms of Algæ, with the special object of determining whether the filamentous forms Scytonemeæ, Oscillarieæ, &c., and the non-filamentous or Chroococcaceæ may be different stages of development of the same organism. Pure material was obtained by allowing the filaments of the alga under examination to creep along the wall of the vessel, and collect above the level of the water in tufts or pellicles. These were then cultivated in boiled water or on disks of porous clay, which had also been exposed to a high temperature, and placed in large glass vessels in moist boiled sand. The dead cells of water-plants, as *Lemna, Utricularia*, &c., and the shells of certain of the lower animals, like *Cypris*, were also used as nurseries for the filamentous Schizophyceæ, and in them the formation of chroococcaceous forms was especially well followed out.

The author describes in detail the development under these circumstances of nine different filamentous species; and arrives at the following general conclusions:—(1) That the relationship between the Schizophyceæ and the Schizomycetes is much closer than has hitherto been generally believed, confirming the classification adopted by Cohn and Sachs of including these two families in the same group of Schizophyta. (2) That a new impulse is thus given to the study of the Schizophyceæ. (3) That the formation of zooglœa is a more widely spread phenomenon than has hitherto been supposed, as is illustrated in Cienkowski's observations on *Ulothrix*, *Cylindrocapsa*, and *Glœothamnion*. The results obtained tend also to the conclusion that many other members of the group of Chroococcaceæ are merely stages of development of filamentous Schizophyceæ.

Motion of Diatoms.—Prof. Hamilton L. Smith considers [*] that Mr. C. M. Vorce's paper on this subject [†] is marked by careful, well-matured statements, and that the conclusions at which he has arrived are quite correct. He has not the least doubt that the diatoms are enveloped by a membrane, out of which the stipes, tubes, &c., are formed. "The movements, so curious and so varied, are yet connected with the structure of the frustule, and we must not ignore this in attempting to explain them, e. g. the *Nitzschiæ*, which have a continuous raphe, that is, without median nodule or break, move in the most lively manner, they are also long and slender; the stalked forms move when free, *Cocconema*, for example, in a long curve, *Gomphonema*, straight; the *Navicula* group move in straight lines, but not in so lively a manner as the *Nitzschiæ*. All these, except the last named, have a median nodule. The *Surirelleæ*, which have the raphe along the four expansions, or *alæ* (two for each valve), move more sluggishly, rolling over frequently, and the *Amphiproreæ* and other twisted forms rock or twist as mentioned by Mr. Vorce, while the circular forms, like *Coscinodiscus*, which have the raphe probably all round the margin of the cingulum or connecting zone and edge of the valve, do not move at all, or if so, very sluggishly. The movement then is more or less regulated by the structure of the frustule, and in any explanation we must not forget this. The careful observation of facts meanwhile should not be neglected, and the publication of them may give the clue or hint that will guide some other observer, possibly, to the true solution of a phenomenon as marvellous as it is at present inexplicable."

MICROSCOPY.

α. Instruments, Accessories, &c.

Lossner's Tele-microscope.*—O. M. Lossner has patented an instrument under this name. The objective forms a reduced image of a somewhat distant object, and this is enlarged by an ocular of four lenses. The construction of some is in hand, and "if successful this instrument, even if only for small enlargements, will, without doubt, be a welcome tool for the observation of living insects, &c."

Prazmowski's Micrometer Microscope. — This Microscope (Fig. 91) was designed by M. Prazmowski for investigations in

FIG. 91.
which measurements are to be recorded, and when it is also required to note precisely the angle of the illumination, &c., for purposes of repetition. We believe that it was made upon a special order (and not subsequently reclaimed), so that M. Prazmowski must not be

* Centr.-Ztg. f. Opt. u. Mech., iii. (1882) p. 108.

considered as endorsing any practical value in the instrument as a whole.

The principal micrometric movement is controlled by the graduated milled head A working on a fine steel screw against springs, by which the rectangular framework carrying the *optical body* is moved in a direction at right angles to the vertical main limb and parallel with the stage. The optical body, with rack and pinion for coarse adjustment, fits loosely into this carrier; it can be adjusted concentrically with the rotating stage by the action of side screws together with the micrometer-screw at A, and can be clamped in position by a screw-collar beneath. The fine-focussing is effected by the micrometer-head B working on a screw against a spiral spring on the main limb; the whole of the optical portion is thus moved together in focussing, as is usual in Continental Microscopes. The eye-piece has a goniometer circle C attached, and is provided with a movable disk of glass with crossed lines in the usual position of the eye-piece micrometer, by which accurate determinations of angles in azimuth can be made while the object is stationary, &c. The *rotating stage* is of simple construction, similar to that on ordinary "turntables"; it is held in position by an indented key-piece (metal knob shown under stage) that slides into a circular rotating groove beneath, and can be removed at pleasure—the main rectangular stage is then only $\frac{3}{16}$th inch in thickness, and is fitted with a wheel of diaphragms, also removable. The *mirror* D is mounted in a gimbal sliding on a bar with lateral motion; the three axes of motion are each provided with a graduated disk and pointer, so that exact record of the position can be made. The *condenser* E is mounted to slide on one of the feet, and can be adjusted variously to direct the light upon the mirror. The two back feet close up against the front one for convenience of packing.

Simplified Reading Microscope for horizontal and vertical circles.[*]—Herr Hensoldt, of Wetzlar, claims to have made a great improvement in the application of the compound Microscope to instruments of *medium* size, such as theodolites of from 12 to 20 cm. in diameter of limit. Whilst universally used for the larger, especially astronomical instruments, a Microscope has been found to be inconvenient for others, principally on account of the projecting micrometrical screws and the length of the body hitherto found necessary.

The author says that he "has succeeded in reducing the length of the Microscopes to a most considerable extent by the selection of favourable qualities of glass, and by suitable construction of the lenses. With a power of from 45 to 50 diameters, they only possess a length of 5 cm. and an outer diameter of 16 mm., reading up to 12″, and between the objective and the division there is sufficient room to affix a little illuminator, which throws a more than sufficient amount of light on the division. The latter appears very clear and distinct, and if the limb is provided with a glass cover, the objectives of the Microscopes are constructed accordingly, so as not to lose in definition.

[*] Zeitschr. f. Vermessungswesen, viii. Transl. in Eng. Mech., xxxiv. (1881) pp. 83-4 (1 fig.).

"The Microscopes are provided with adjustable eye-pieces, to render the division of the micrometer distinct for every eyesight, and at the lower end is a short draw-tube, by means of which a small alteration in the magnification can be effected, whereby the intervals of the micrometer (previously determined by calculation) can be brought to accurately harmonize with the division of the circle.

"As the field of view, though as extensive as possible, cannot be so large as to always include figures of the divided circle, an index with a magnifying lens must be fixed at any desired point, by means of which the reading of the angle up to the nearest division of the circle is obtained, while the determination of the excess is effected by the Microscopes."

The divisions of the circle with which the Microscopes are used are not carried to any great degree of minuteness. The degrees are, for instance, divided into sixths, or 10', and the micrometer consists of ten equal divisions, representing, therefore, minutes, and the latter can then be mentally subdivided with great facility. An important advantage is, the author considers, obtained by the *small number* of graduations of the micrometer, which permits an easy, rapid, and accurate reading, which does not occupy so much time as in the case of verniers.

Swift's Tank Microscope.—This, Fig. 92, consists of the stand of a bull's-eye condenser to which are attached two additional short arms, the upper one carrying the microscope-tube and the lower a revolving cork-holder and forceps for flowers or other objects suitable for low powers. The tube has a rack-and-pinion movement and the arm to which it is attached can be raised or lowered on the standard and clamped in any position. The tube can also be rotated on the arm so as to be either vertical or horizontal, or it can be removed from the arm altogether.

Fig. 92.
Teasdale's Field Naturalist's Microscope.—This (Figs. 93 and 94) is made by Messrs. Field of Birmingham, and was designed by Mr. W. Teasdale with the view of providing the working microscopist with a really cheap and efficient dissecting Microscope, and it may be readily certified that it fully accomplishes these objects. "It is so simply and substantially made that it

Fig. 93.
Fig. 94.
may be used by an intelligent child, as well as by the experienced microscopist. It was termed a 'Field Naturalist' rather than a 'Dissecting' Microscope to disarm the suspicion with which some people look upon an instrument with the latter name as a rack or means of torture for frogs, &c."

The woodcuts render any detailed description of the instrument unnecessary, and we need only call attention to the sloping rest for the hands and that there are three lenses, a condensing lens, forceps, and live-box. The lenses drop into the arm which carries them, and also into each other, so that they may be used in combination, producing seven powers in all.

Marshall's turntable can also be used with the instrument, the spindle passing through a hole in front of the stage, and its point revolving in a brass socket below.

Steinheil's Achromatic Eye-pieces.—These eye-pieces ($\frac{3}{4}$ in. and $\frac{1}{3}$ in.), exhibited and described by Mr. Ingpen at the June meeting of the Society, are shown in Figs. 95 and 96 in section. They are especially adapted for micrometry. They consist of a double convex lens of crown between two meniscus lenses of flint, all cemented together. Grooves cut in the edge and blackened, form diaphragms as in the Coddington lens.

Fig. 95.   Fig. 96.
New Combination for Objectives.[*]—The following is the whole of the note by C. V. Zenger under this heading published in the 'Comptes Rendus':—

"The author proposes to obtain an amplification equal to 2000 with a large focal distance. It would then be possible for anatomists and physiologists to carry on their dissections and preparations with a very considerable amplification, at a distance from the objective equal to 4 mm. or 6 mm."

Fluid for Homogeneous Immersion.[†]—Professor Abbe finds that pure cedar-oil may be prepared so as to render it much less fluid than in its ordinary condition. By spreading it out in thin layers and exposing it for a long time to the influence of air and light, it becomes of the consistency of castor-oil, and without any increase in dispersive power, its refractive index is raised to $1\cdot518$–$1\cdot520$. If desired, the index can of course be reduced to $1\cdot510$ by the addition of olive or castor oil.

Dr. L. Dippel considers that this fluid unites in itself *all* the properties required for such a fluid, and that it makes all others superfluous.

Shurley's Improved Slide for the Examination of Gaseous Matter.[‡]—Dr. E. L. Shurley describes an apparatus for the examina-

[*] Comptes Rendus, xciv. (1882) p. 1542.
[†] Bot. Centralbl., x. (1882) pp. 224–5.
[‡] Proc. Amer. Soc. Micr., 4th Ann. Meeting, 1881, pp. 65–8 (1 fig.).

tion of aerial or gaseous material, with the higher power of objectives, without subjecting it to any previous manipulations, thus enabling one to collect and immediately examine with any objective, " even a $\frac{1}{25}$ or perhaps a $\frac{1}{50}$ inch." The apparatus consists of a rubber bag (Fig. 97) with a tapering, hard rubber nozzle, into which is inserted a perfectly tight fitting stopcock. A piece of soft rubber tubing $\frac{1}{8}$ inch in diameter and about 2 feet long is furnished at one end with a metal collar, to be inserted into the outer end of the brass canule of the slide; while the other is to be slipped over the nozzle of the bag. The larger extremity of a small canule about $1\frac{1}{2}$ inch long, is fixed by a binding screw into the upright B on the glass slide, while its small end is inserted into the minute hole at the side of the cell. The larger extremity is smoothly ground, to receive the metal-finished end of the conducting tube. The slide has an ordinary cell A (of rubber).

The cell has its middle portion built up from the bottom by a piece of glass, so as to bring it within the working distance of the objective, allowing depth enough at the sides, which may be compared to two ditches, for the introduction of a canule of reasonable

Fig. 97.
calibre. This, the author says, is an important point, inasmuch as a cell shallow enough for the adjustment of its bottom to the focus of a first-class $\frac{1}{8}$-inch objective, could have a depth of only about a fortieth of an inch, and of course for higher powers less, altogether too shallow to allow of the introduction of a canule of practicable size. But, upon this plan, the cell may be built up ever so much, even for adjustment of a $\frac{1}{50}$-inch objective, while yet at its sides will remain the same depth of ditches, or *sulci*, for the ingress of the gas.

The cover-glass may be cemented on, or laid on loosely. In the former case the opposite side of the cell must be perforated to allow

the gas to escape, while in the latter case it escapes by itself lifting
up from time to time the cover-glass.

As all objects or particles contained in the air or gas must be
at rest when examined with the higher power objectives, it will be
necessary to coat either the bottom of the cell, the cover-glass, or
both, with something to which the material will adhere as the gas
passes through. One of the best methods is to coat both the bottom
of the cell and under side of the cover-glass with a thin layer of
glycerine—somewhat after Beale's method of collecting aerial germs.
This coating is easily accomplished by previously moistening the
glass with alcohol. The rubber bag and connecting-tube may be
cleansed by drawing alcohol into them, and after expelling this they
may be easily dried, if desired, by drawing and expelling air for
awhile.

All the parts being in proper connection, by opening the stop-
cock of the receiver, and gently pressing upon it, the cell may be
supplied at will. As before stated, any gaseous material can be
collected and kept any length of time from the access of air, and
when desired, *directly* examined under the Microscope without any
intermediate manipulation; "a great desideratum and one which
cannot be attained so far as I have been able to learn, by any other
slide or apparatus hitherto in use. Those most used are the
'Stricker' and 'Hunt' gas slides, the Holman 'life slide,' and the
animalcule cell or cage, none of which is applicable in examinations
with the higher power objectives; and none of which, excepting one,
is arranged so as to allow of the direct introduction in small quantity
of gaseous material. The advisability, nay, the necessity, of more
perfect means for the examination of aerial or gaseous matter, must
have been felt by every one who has ever attempted any work in this
direction : and it is obviously only by patient investigation with high-
power objectives that we can hope to discover the nature and habitat of
those infinitesimal organic poisons which are supposed to originate
in some unknown way the so-called zymotic diseases."

Hardy's Compressorium.[*]—Mr. J. D. Hardy's object in con-
structing the compressorium shown in Fig. 98, is to remedy, to some
extent, the defects of existing compressors as regards the difficulty

FIG. 98.
of regulating the pressure with exactness, the imperfect parallelism,
and a deficiency of freedom of action, which causes great risk of
losing or damaging the object under observation.

* Journ. Quek. Micr. Club, i. (1882) pp. 35–6 (2 figs.).

A is a brass plate, 3 inches by $1\frac{1}{2}$ inch, in the centre of which is a round hole. At one end is a bent spring B, of thin brass, to which is hinged a second brass plate C, also with a central round hole, and bevelled on the upper surface for high powers. This second plate will, when turned down, overlie the plate A, and the two apertures will correspond. At the other end of the plate A, a button D is mounted so as to turn freely, and to rock on a short stud pin d. The outer extremity of this button is bored and tapped to receive a small thumb screw e. A similar thumb screw f is also fitted to the plate C, near its hinge joint.

A thin cover-glass is cemented to the upper side of the plate A, so as to cover the central hole, and the under side of the plate C is similarly provided.

The mode of using this compressor is as follows:—The plate C is first turned down into place, and the distance that it is desired the glasses should be apart roughly adjusted by means of the screw f. The plate C may then be turned back, and the object placed on the lower glass; the covering-plate is then again turned down and secured by turning the button D over it. By means of the two screws d and f, the pressure can now be regulated with the greatest nicety without any risk of damaging or losing the object under examination. The arrangement admits of the glasses being easily cleaned and readily replaced by new ones when broken.

Bulloch's Diatom Stage.[*]—Mr. W. H. Bulloch has made a supplementary stage for use in arranging diatoms. It fits into the substage ring, and a stem projects up through the hole in the main stage. Upon the stem there is an arrangement like a double nose-piece, which carries two glass slips. One of the slips is intended for the material from which the diatoms are to be selected; the other for the prepared slide upon which they are to be mounted. The two slips can be moved about independently upon their supports. The hair or bristle is mounted on the mechanical stage. The slide carrying the material is first focussed, the diatom picked up, and the supplementary stage turned until the clean slide is in focus, when the diatom is placed in position.

Substage Fine-adjustment.—At the suggestion of Mr. E. M. Nelson, Messrs. Powell and Lealand have recently applied a fine-adjustment to their substage specially for use with their achromatic condenser. Fig. 99 shows (half-size) the under side of the substage with the new fine-adjustment in which A is a milled head controlling a screw-spindle terminating in a steel cone B. On rotating A, B turns and with a very slow motion forces up (or releases, as the case may be) a pin C inserted in the base-plate E of the substage. This motion of C carries with it the condenser. At right angles to, and forming part of E, at the back, an inner sliding plate works against a spring at the upper end between bearings F at each side, which are fixed upon the usual racked slide D of the substage; this inner

* Amer. Mon. Micr. Journ., iii. (1882) p. 97.

sliding plate is the essential addition to the usual racked slide in the application of the new fine-adjustment to the substage. The range of motion is about $\frac{1}{8}$ inch — the difference in radius between the smaller and larger ends of the steel cone.

Mr. Nelson states that he has found the fine-adjustment on the substage of service in difficult investigations with the condenser in the axis. By this means he can readily exhibit the transverse lines of *A. pellucida* without any diaphragm.

Sidle's Centering Substage. —We gave a figure of Messrs. Sidle's "Iris" diaphragm in Vol. III. (1880) p. 1053, and briefly alluded to the centering arrangement of the substage as "a short bar working with a loosely fitting slot, that can be clamped beneath," which is characterized as a somewhat primitive contrivance. Messrs. Sidle now adopt in their "Acme No. 2 Binocular," the method of centering shown in Fig. 100, the special feature of which is that the substage motions are controlled by two milled heads (right and left) on the arm or bar-attachment at the back of the substage carrier, racking on the swinging tail-piece. By this system the usual *outer* substage-ring, with its projecting centering screws (so generally adopted in America), is done away with. The forward motion is given by the left-hand milled head acting on rackwork; the lateral motion by the right-hand milled head acting on a pointed screw against a U-shaped spring that presses the slide towards that side, the fixed end of the spring being attached to the main base- or angle-plate racking on the tail-piece.

FIG. 99.

FIG. 100.

We have not yet seen this mechanism, but with good workmanship we should anticipate the plan to be practical—certainly much better than the former system of centering by the rough process of pushing, pulling, and clamping by hand, which did not suggest the possibility of accurate centering.

Mounting for the "Woodward" Prism.[*]—Dr. J. Edwards Smith recommends the form of mounting the "Woodward" prism shown in
* 'How to Work with the Microscope' (8vo, Chicago, 1880) p. 171 *et seq.*

Figs. 101 and 102 (where in Fig. 101 A is a vertical view, and in Fig. 102 B a sectional view, and C the prism three-fourths full size). He states that this accessory is easily placed in position in the well-hole of the " Acme " stand, and that doubtless with slight modifications this system of mounting the prism may be applicable to other Microscopes. Provision is made for centering in a lateral direction

FIG. 101.
FIG. 102.

by means of the milled head at A. The prism can also be revolved by the milled head shown below so as to use either face, the faces being cut at different angles. Regarding the angles of the prism-faces, he thinks 98°, 41°, and 41°, as suggested by Dr. Woodward, are good ; but that 93°, 47°, and 40°, which he has himself adopted, are especially adapted for the general run of modern wide-apertured objectives. He gives detailed instructions for the use of the apparatus and thinks that it " bids fair to come into general use."

Prisms versus the Hemispherical Lens as Illuminators.—In various catalogues issued by American opticians, references are also made to sundry forms of mounting for the " Woodward " prism. It appears to us that much ingenuity is being wasted in such efforts, for whatever may be the angles of the prism-faces, the hemispherical lens must necessarily entirely supersede it, having in fact an infinite number of facets through which normal light may reach the common centre. There may of course be cases where a small beam of parallel rays

directly transmitted by the plane prism-face may be thought to produce the purest effect of oblique illumination; but in our experience wherever oblique light is required for the resolution of striæ, &c., the slight condensation of rays produced by the curved surface of the hemispherical lens is no detriment, but rather the contrary, whilst for facility of manipulation the lens is greatly to be preferred.

Mounting the hemispherical lens on a plate to be put immediately beneath the slide is not to be commended, for every movement of the slide then carries the illuminator with it, and the direction of the light requires continual readjustment. No better plan of applying the lens has been suggested than that adopted by Tolles and Ross, in which it is mounted to slide or screw into the stage-aperture from beneath. This plan is applicable to nearly all the modern Microscopes having mechanical stages.

For the Microscopes generally used on the Continent, without mechanical stage-movements, the hemispherical lens may be mounted, as suggested by Professor Abbe, in a disk of metal made to drop into the stage-opening from above so that the plane face is flush with the level of the stage.

Radial Tail-pieces.—Since the introduction of the Zentmayer swinging tail-piece or swinging substage in 1876, several opticians have carried out the same principle, but instead of the pivot motion of Zentmayer a disk is applied at right angles behind the stage in which a movable zone is fitted to carry the tail-piece. In all the Microscopes we have inspected in which this plan is adopted, we remark that the attachment of the tail-piece is so slight as seriously to interfere with the firmness of the substage. This is a great inconvenience in all manipulations of the substage; the rackwork, centering-screws, diaphragms, mirror, or whatever may be attached to the tail-piece, cannot be touched whilst the eye is directed through the Microscope, without the flexure of the tail-piece causing the illumination to move from the field of view. Of course this applies only to the use of high powers, but all such Microscopes are supposed to be made specially for high-power work.

Electric Light in Microscopy.—Referring to his previous paper on this subject,* Dr. Van Heurck sends us the accompanying Fig. 103, showing the Regnier battery which he has adopted in place of the Tommasi; the sulphate of copper being placed in the small basket at the left-hand side of the cells.

The Regnier accumulator is also shown in Fig. 104.

Dr. Van Heurck adds that the Regnier battery can be placed in the laboratory of the microscopist, as it does not give off any vapours. It will remain charged for at least a month if sulphate of copper is added as required. Sixty-four Regnier elements (each = 1·07 volts), charging sixteen accumulators, lighted a great part of his house for six weeks. They can be used with only one accumulator, to act as a

* See this Journal, *ante*, pp. 418–20.

Fig. 103.
Fig. 104.
regulator of the current. If expense is not an object four accumulators may be used (requiring sixteen elements), the accumulators thus serving both as regulators and reservoirs, and allowing several lamps to be used at a time. The particular Swan lamps he uses are the " $2\frac{1}{2}$-candle " lamps.

Still later Dr. Van Heurck says that he is experimenting with some new accumulators of M. de Kabath, which seem likely to give good results.

Black Backgrounds.*— Mr. Tuffen West on principle very much dislikes to see objects mounted with an irremovable black background. When it is desirable to view objects as opaque, there are so many other ways of doing this; e. g. the diaphragm, the dark-well, a piece of dead-black paper, cloth, or velvet placed behind the slide. The object can then still be viewed as a transparent object also. Otherwise it is the mounter saying to the observer, " You shall see my slide as I will, and in no other way."

Micrometrical Measurement by means of Optical Images.†— A paper on this subject was published some time since by Professor Abbe in German, and we at once had it translated with a view to its insertion in this Journal. We must frankly confess, however, our inability to put the paper in proper form for publication here, and as Professor Abbe is much taxed in various ways we have not thought it right to ask him to undertake the matter.

We therefore content ourselves with a translation of a German abstract of the article. ‡

" E. Abbe has turned his attention to the study of the Microscope as used with a micrometer, and finds that the sources of error belonging to the present methods of measurement can be obviated by using ' telescopic ' systems of lenses instead of the ordinary objective with a finite focal distance. Such a glass is made up of two separate lenses or systems, whose focal planes are turned towards each other and coincide. It has an unlimited focal length, and the focal points lie at an infinite distance; all objects are reproduced with an enlargement which may be determined at will, but is constant; so that this magnification remains *independent alike of the distance of the object, that of the image, and of the length of the tube.*"

Malassez's Improved Compte-globules.—Professor L. Malassez in 1880 published § a detailed paper on corpuscle-counters in which the various devices of himself, Hayem and Nachet, Gowers and Zeiss were fully referred to with a statement of their respective advantages and disadvantages, and in which he described an improved apparatus suggested by himself. An epitome of the paper by Mrs. Ernest Hart with critical observations has also appeared in English,‖ so that it is unnecessary to refer to it otherwise than briefly here.

* Journ. Post. Micr. Soc., i. (1882) p. 94.

§ Arch. de Physiologie, 1880, p. 377.
‖ Quart. Journ. Micr. Sci., xxi. (1881) pp. 132–45 (3 figs.).

The improved apparatus is shown in Fig. 105. It is made by **M.** Vérick, and consists of a thick brass slide, having in the centre an

FIG. 105.
FIG. 106.
aperture, into which is fixed a circular glass block about a centimetre in diameter, with its upper surface level with the top of the slide, and

surrounded by a groove about half the thickness of the slide in depth. Outside this groove are three pointed metal screws equidistant from each other, the elevation of which above the surface of the slide is exactly $\frac{1}{5}$ mm. In the centre of the glass block the squares are drawn in which the corpuscles are counted. The sides of these are $\frac{1}{20}$ mm., and they are arranged in groups of twenty, as shown in Fig. 106 ($\times$ 200).

To facilitate lowering the cover-glass so as to be exactly horizontal, M. Malassez devised the frame (Fig. 105) to the underneath part of which the edges of the cover-glass are attached by a little water or saliva. The frame is supported on two arms attached to one flange of

Fig. 107.
a hinge, the other flange being secured to the slide by a clasping screw. The frame with the cover-glass is raised or lowered by the longer of the two arms, and the operation may be quickly performed. A small spring clip keeps the whole down so that there is no danger of the cover being raised or displaced.

Fig. 108.
The mixing of the blood is effected in the "Mélangeur Potain," shown in Fig. 107, and the whole apparatus, with triangular knife for making incisions, cover-glass, and a bottle of diluting liquid, packs into a small pocket-case $13 \cdot 5 \times 8 \times 2 \cdot 5$ cm. (Fig. 108).

Cutting and Mounting Microscopical Sections.[*]—Mr. A. G. Bourne describes some modifications of older processes, which he considers constitute the latest stage of development of the section-cutter's art.

Hardening.— Any of the ordinary hardening methods may be used, but it is essential that all trace of acid should be removed in order to obtain good staining results. Corrosive sublimate is an exceedingly useful hardening reagent, and tissue treated with it stains as readily as if treated with alcohol only. The solution used is a concentrated one. The fresh tissue or living animal is placed in it for fifteen to thirty minutes, according to its size; it is then washed in water and transferred to alcohol of 50 per cent.—a large relative bulk of this must be used, and the tissue well permeated by it, otherwise some

* Quart. Journ. Micr. Sci., xxii. (1882) pp. 334–7.

corrosive sublimate is left in the tissue and is thrown down in needles when strong alcohol is added. After 24 hours the tissue is transferred to alcohol of 70 per cent., and after 24 hours to alcohol of 90 per cent., and then to absolute alcohol. With large pieces of dense tissue this should be changed once or twice. After two or three days the tissue is ready for staining. If time is an object, and no acid has been used in the hardening, the tissue may be transferred directly from alcohol of 70 per cent. to the staining fluid; but it is advisable, and in the case of delicate tissues necessary, to complete the hardening process before staining.

Staining.—Grenacher's alcoholic borax carmine is used. Pure carmine (2·5 per cent.) is added to the solution of borax (4 per cent.), in water; this is allowed to stand for two or three days, and occasionally stirred—the greater part of the carmine will dissolve. To this solution is added an equal bulk of alcohol of 70 per cent. This mixture must stand for a week and then be filtered, when it is ready for use. If on keeping more carmine is deposited, it should be refiltered.

The tissue is placed in this solution, and allowed to remain one, two, or three days according to its size; it is hardly possible to overstain, and there is sufficient alcohol in the solution to prevent injury to any but the most delicate tissues. For such tissues a solution can be prepared containing more alcohol, but of course less carmine.

The tissue when removed from the staining fluid is placed in alcohol of 70 per cent., acidulated with hydrochloric acid (3 to 6 drops of the acid to 100 c.c. of spirit). This dissolves out all excess of carmine and fixes the rest. The tissue, a dark purplish-red when taken out of the borax carmine, should be left in the acidulated alcohol till it acquires a bright transparent look (3 to 6 hours), it may then be transferred to absolute alcohol and afterwards to turpentine. When thoroughly permeated with this latter (the time necessary varying as the size of the lump of tissue) it is ready for imbedding.

Imbedding.—This is done in paraffin, and it is exceedingly important to obtain a suitable paraffin. It should melt at 100° or 115° F. Paraffin of various melting points should be kept in the laboratory; they may be purchased at the dealers.

The tendency to curl up on the part of the section may be reduced to a minimum by obtaining a paraffin of the proper consistency, but this seems to vary according to the temperature of the room in which the sections are cut.

The paraffin must be melted in a small covered vessel in a water-oven, great care being taken to keep it in a dry atmosphere. The temperature in the oven should never rise more than two or three degrees above the melting point of the paraffin used.

When the paraffin is melted the tissue is removed from the turpentine and placed in it, and this must be kept at its melting point for some hours until the tissue is thoroughly permeated; it may then be poured into a paper trough, watch-glass, or any other vessel, and allowed to cool.

Cutting.—There are two forms of microtome suitable for cutting sections in series. In one the tissue is raised directly by a fine screw, and the sections cut with an ordinary razor: in the other form, now so largely used, the tissue in its holder is moved up an inclined plane, and the sections cut with a large knife which works backwards and forwards in a horizontal slot running parallel with the inclined plane. In both cases the machine is fixed to the table or heavy enough to remain steady, so that while the razor is worked with one hand the other hand is at liberty to hold a little paper spatula—a small piece of paper run on at the end of a small scalpel—to prevent the sections curling. The paraffin block is pared down to the smallest size possible, and, as the razor is drawn along, the edge, which commences to curl, is caught by the paper and prevented from so doing; the section is then transferred to the slide.

Preparation of the Slide.—The slide is smeared with a strong solution of shellac in anhydrous creosote. Care must be taken to have as little as possible on the slide. By this method the sections are stuck to the slide, thereby saving the most delicate objects from falling to pieces after the paraffin is removed, and enabling one to mount numerous sections on one slide. The importance and value of this treatment cannot be over-estimated. It enables one to mount with absolute certainty whole sections of the most friable objects, such as an insect, without a single fragment of the section becoming displaced.

Mounting.—The slide bearing the sections is now placed in a water-oven or on a tin box containing water at a temperature two or three degrees above the melting point of the paraffin used. The slide is left here for at least half an hour. The object of this warming is twofold, to evaporate the creosote and to melt the paraffin.

The slide is now taken up, and while the paraffin is still molten is flooded with turpentine dropped from a small pipette. This dissolves melted paraffin instantaneously, and precipitates the shellac fastening the sections to the slide. The turpentine is allowed to flow off, and replaced by new until all the paraffin is removed. The slide is then allowed to drain, the edges wiped, and the cover-glass put on. The Canada balsam, which should be very fluid, is placed on the under surface of the cover-glass; this is turned over and quickly lowered. The balsam dissolves the shellac, and if the cover-glass is not put on very quickly the sections may shift or delicate sections come to pieces and float off the slide. It being necessary to use the balsam in such a fluid condition, and a certain amount of turpentine always remaining upon the slide, the slides should be looked over the next day and more balsam added at the edge of the cover-glass if necessary. These methods, especially that of fastening the sections to the slide with shellac, although suggested and elaborated by zoologists for the purpose of mounting serial preparations, will, no doubt, come into very general use in ordinary histology for such tissues as placenta or spleen where very thin sections have always been found liable to fall to pieces, and the most important pieces to fall out and be lost.

Preparing Blastoderm of the Chick.—C. Koller,[*] who has taken up this subject in order to decide some disputed points in the embryology of the chick, thus describes the method by which his preparations were made.

The egg was subjected to the hatching method recommended by Kölliker. At the proper time it was opened and its contents carefully transferred to a glass; as much of the albumen as possible being removed by the fingers or otherwise. In order to keep a note of the exact direction in which it was wished to take the sections, it was generally found necessary to make an indication on the egg while still fresh, as in the earlier stages the appearances in the surface of the yolk are rendered indistinct by the process of hardening; to this end, Koller has been accustomed to insert with forceps a small triangular pointed slip of paper into the yolk immediately behind the germinal disk in such a way that it indicates the extreme posterior margin of the blastoderm, and lies at the same time in the median plane of the future embryo. The yolk is now submitted for twenty-four hours to the action of a $\frac{1}{10}$ per cent. solution of chromic acid, and then for another twenty-four hours to one of $\frac{1}{5}$ per cent., and thus increasing the strength daily up to $\frac{1}{2}$ per cent. If the yolk is sufficiently hardened, the segment on which the blastoderm lies, together with the central mass, is detached with a fine scalpel and immersed in distilled water for twenty-four hours to remove the superfluous chromic acid. The yolk-membrane may be very readily removed from the hardened germ without injuring the latter. The blastoderm is stained entire with weak ammoniacal carmine (length of staining twelve to twenty-four hours), then washed by twenty-four hours' immersion in distilled water and placed in absolute alcohol. It is ready for cutting in from one to two days. After lying for a few minutes in oil of cloves it is imbedded in a mixture of wax and oil. Sections are made by hand, using turpentine to moisten the object.

Preparing Embryos of Insects.†—In a paper on the embryonic development of the Bombycidæ, Dr. S. Selvatico describes the methods he has made use of both for the preparation of entire embryos and for sections. The species employed were *Bombyx mori*, *Attacus Mylitta*, and *Saturnia pyri*.

The eggs are first coagulated by plunging them in water at 75° C. With a pair of fine-pointed forceps a small piece is removed from the shell, in the case of *Bombyx*, without disturbing the underlying parts. With a little care this is easily done, because on the eggs becoming cold their contents are somewhat contracted and do not touch the shell. In the case of *Attacus* and *Saturnia* the eggs have a harder shell but are larger, and a razor was employed by the author.

They are then hardened by leaving them for twelve hours in a ·002 per cent. solution of chromic acid, and for twelve hours more in a ·005 solution. Then with a little care the shell can be easily

* Arch. Mikr. Anat., xx. (1881) pp. 181–2.
† Journ. de Microgr., vi. (1882) pp. 220–1.

removed by employing the forceps or cutting it round with a razor.

The entire contents having been removed the egg is freed from chromic acid by leaving it in 30 per cent. alcohol for a day, the alcohol being renewed until it is no longer coloured yellow.

For staining, the egg is placed in picrocarmine for twenty-four hours and washed in 30 per cent. alcohol to remove the picric acid. When it has been well washed it may be kept in 30 per cent. alcohol until sections are required.

Previous to cutting sections the egg should be placed in absolute alcohol for half an hour, and then for a few moments in essence of bergamot. Dry and imbed in a mixture of 4 parts of spermaceti and 1 of cacao butter, to which is added, according to the temperature, some drops of castor-oil. The knife should be moistened with olive-oil and each section washed with a mixture of 4 parts of oil of turpentine and 1 of creosote to dissolve the imbedding substance surrounding the section. Mount in Canada balsam.

To preserve the embryo entire, the shell is to be removed as above described, after coagulation. The egg is then placed in a drop of water on the stage, and with a low power the embryo is extracted from the vitellus. It is cleaned as much as possible, so that no portion of the vitellus adheres to it, and mounted in glycerinated gelatine, previously coloured with methyl-green. By this method the embryo takes from the gelatine an excess of colour, and is thus stained after the preparation is made. If it is coloured first and then placed in colourless gelatine it will always lose colour (sometimes completely) if the gelatine is only a little greater in volume than the embryo.

Collecting, Staining, and Photographing Bacteria.*—Dr. G. M. Sternberg in " a contribution to the study of the bacterial organisms commonly found upon exposed mucous surfaces and in the alimentary canal of healthy individuals " (which contains much interesting matter), states that he has found the following to be the most satisfactory method of collecting bacteria for examination with high powers and for photography.

The slightest possible smear of the material to be examined is allowed to dry upon a thin glass cover, and to secure a sufficiently uniform layer, it is usually best to spread it while moist with the end of a glass slide. Material is obtained from the mouth by scraping the surface of the tongue, or of the teeth, with a clean instrument ; from the female vagina by a speculum or digital examination ; and from the male urethra, by applying a thin glass cover directly to the moist mucous membrane at the extremity of the canal.

A five-cent bottle of aniline violet ink furnishes an ample supply of staining fluid of the best quality. Two or three drops of this placed upon the thin cover will very quickly—one to three minutes— give the bacterial organisms attached to its surface a deep violet colour. The cover is then to be washed by a gentle stream of pure water, and is ready for immediate examination, or may be mounted

* Stud. from the Biol. Lab. Johns Hopkins Univ., ii. (1882) pp. 157–81 (19 photomicrographs).

for permanent preservation over a shallow cell containing a solution of potassium acetate (Koch's method), carbolic acid water (2–5 per cent.), camphor water, or simply distilled water.

To make satisfactory photographs of the smallest bacteria, it is necessary to use a staining fluid which will give a stronger photographic contrast, as the violet is transparent for the actinic rays. For this purpose aniline brown (recommended by Koch) may be employed, or iodine solution (iodine 2–5 grains, potassium iodide q. s. to dissolve, distilled water 100 grains).

A recent writer (Soubbotine *) advises the use of osmic acid as a fixing solution to be used in advance of staining. This is doubtless desirable when specimens of blood or thin sections of tissue containing bacteria are to be examined, as the normal histological elements are better shown, but the method possesses no special advantages so far as the demonstration of vegetable organisms is concerned. It must be remembered that aniline solutions often contain a granular precipitate which might be mistaken by a novice for deeply stained micrococci.

Ehrlich's Method of Exhibiting the Bacteria of Tuberculosis.†— Dr. Ehrlich, Prof. Koch's assistant, has lately explained ‡ a new method of preparing tuberculous bacteria, which is a great improvement on the original process of Koch. It renders the demonstration much easier, and its results are so certain, that it may be applied to establish the diagnosis of the disease in doubtful cases. The preparations made according to the method recommended by Koch in his first paper (i. e. double staining by alkaline methylene-blue and vesuvin §) have left doubts in the minds of some observers, which they could not have had if they had seen the preparations obtained by Ehrlich's process which Koch himself has now adopted in preference to any other.

Tuberculous bacteria as well as all the micro-organisms, bacteria, or micrococci, have a great affinity for aniline colours, and are strongly stained by them. Koch's researches have shown that the bacteria of tuberculosis have special and characteristic properties, and that their cellular membrane is very easily penetrated by alkalies. It is upon this experimental fact that Koch based his ingenious method, which consists essentially in impregnation by an aniline colour, rendered alkaline by the addition of a small quantity of caustic potash.

But this alkali exercises a modifying action on the different histological elements and on the bacteria themselves. Under its influence the albuminoid corpuscles swell to excess, and the coagulated layers of morbid matter are easily detached from the cover-glasses. Ehrlich, therefore, sought for another base, acting in a less powerful manner, and found it in *phenylamine* or *aniline*. Other alkaloids, perhaps even vegetable alkaloids, which can be transformed into colouring matters by means of various reagents, might be equally useful.

§ Cf. this Journal, *ante*, pp. 385–8.

The following is Dr. Ehrlich's method of procedure, which does not present any technical difficulty, and does not require more than an hour to make a dozen preparations. By means of a dissecting needle a particle of expectorated matter, about the size of a pin's head, is taken up and spread between two cover-glasses, * in two exceedingly thin layers on each. The cover-glasses are then separated by sliding one on the other, and left to dry protected from the dust. After a few minutes they are dry, and the fixing of the albuminoids and mucin is proceeded with. For this they can be warmed for an hour at 100° or 120° C., or which is simpler, rapidly passed four or five times through the flame of a spirit-lamp. To colour the preparations a saturated solution of phenylamine is to be made in distilled water,† by shaking with the water the excess of aniline which floats on it, and carefully filtering the whole. To the transparent liquid thus obtained add, drop by drop, a saturated alcoholic solution of *fuchsine* or *methyl-violet* until a slight opalescence is produced. The preparation should not be immersed in the colouring bath, but be placed in such a manner as to float on it, and to have the surface which is covered with the tuberculous matter in contact with the liquid. After a quarter to half an hour the staining is complete.

If examined in this condition it is seen that the preparation is of such an intense colour that it is impossible to distinguish its elements, and Ehrlich happily thought of trying to decolorize it by means of a strong acid ; colourless salts of aniline are then formed, which are very soluble in water and disappear by washing with distilled water. The bacteria, not being penetrated by the acids, preserve their colour. In order to secure that they alone shall be coloured, therefore, it is only necessary to immerse the cover-glasses in nitric acid diluted with twice its volume of water. Nitrous vapours are at once disengaged, and the preparation becomes absolutely colourless in a few seconds. Under the Microscope the bacteria are seen to be very clearly coloured red or violet ; but by reason of their extreme delicacy they often escape the eye and require the most accurate focussing. It is therefore better to study them in preparations which have been slightly coloured blue or green (when fuchsine has been used for the first bath), or yellow (when methyl-violet has been used). They are afterwards mounted in Canada balsam in the usual way.

The advantages of Ehrlich's method are summed up by Dr. E. Van Ermengem as follows :—1st. The aniline alters the form of the histological elements much less than Koch's solution of potash. 2nd. The process is much quicker, and does not occupy more than an hour. 3rd. Its principal advantage is to produce a more intense staining of the bacteria, so that they appear larger, and can be recognized with a lower power, even with 250 diameters.

A question of the highest interest from a medical point of view

* Ehrlich chooses cover-glasses whose thickness is appropriate to the objectives to be employed; those from 0·10 to 0·12 mm. he considers the most suitable.

† The water dissolves about one part in thirty-one at the ordinary temperature, 12° C.

has been raised by Ehrlich with reference to his method. The properties which the membranous envelope of the bacteria of tuberculosis seems to possess, prove that the sole disinfectants or antiseptics which can be used to combat this disease, by acting on the bacteria, *should be alkalies and not acids*, which have hitherto been employed for this purpose.

At the May meeting of the "Société Belge de Microscopie," Dr. Van Ermengem exhibited a series of preparations of tuberculous bacteria obtained from expectorated matter from five patients suffering from pulmonary phthisis of the second and third degree. In each of these cases a few particles of the sputa sufficed to give at least one preparation in which the characteristic bacilli were found.

The first series of preparations were made according to Koch's method. The bacteria were few and difficult to find. They were feebly coloured (a pale blue), and were very small. To show them clearly a very bright light, obtained by means of an immersion condenser, and the use of a good immersion objective were necessary (1080 diameters).

The second series were partly made by Ehrlich's process. The bacteria were coloured a bright red by fuchsine, the rest of the preparation being completely colourless. In one of the preparations the typical bacteria were very numerous, in groups numbering from four to eight within large cells, or disseminated in pairs here and there, and it was not difficult to recognize the spores : often also they were placed end to end in pairs. The organisms corresponded well with the description given by Koch, and were perfectly recognizable without a condenser and without a high power (750 to 800 diameters.)

A few good preparations were also shown in which the ground had been coloured blue. The bacteria were more easily found than in the others, and stood out clearly by their fine red colour from the rest of the preparation (450 diameters).

Specimens of these bacteria prepared by Koch (on his old method) were exhibited by Mr. Watson Cheyne and Mr. E. M. Nelson at the two soirées of the Royal Society on the 10th May and 21st June, and also at that of the College of Physicians, and attracted considerable attention, not only from the interest which attached to Koch's discovery, but also for the excellent way in which they were shown.

Preserving Infusoria and Amœbæ.[*]—E. Korschelt refers to the method described by M. Certes for colouring and preserving Infusoria,[†] in regard to which O. Bütschli in his abstract of the paper expressed a hope that it would be possible to find a more suitable preserving method as he could not place reliance on preservation in glycerine. The author considers that the following method (which he devised without knowing that of M. Certes) will enable preparations to be made which leave nothing to be desired in regard to durability.

The water in which the Infusoria are placed upon the slide must

---

[*] Zool. Anzeig., v. (1882) pp. 217–9.
[†] See this Journal, ii. (1879) p. 331.

be as small in quantity as possible in order to prevent the animals swimming away during the process, which is entirely carried on under the cover-glass. After the cover-glass has been put on a drop of a 1 per cent. solution of osmic acid is added and sucked through from the other side, then water, 70 per cent. and 90 per cent. alcohol, and finally water again. For the colouring of the now sufficiently hardened and fixed animals, Weigert's picrocarmine process * is recommended. This should act an hour and a half to two hours, the preparation being placed in a moist chamber in order to prevent drying. After removal of the colour 70 per cent., 90 per cent., and absolute alcohol, oil of cloves, and finally Canada balsam are added.

This process, which in reality takes only a short time, gives very excellent results for many Infusoria. In the case of others, however, the use of osmic acid is not so good, and with *Amœbæ* it is entirely without result. For these organisms, therefore, a 2 per cent. solution of chromic acid is preferable, which must act for two to three minutes in order to harden them sufficiently, otherwise in washing they readily swell up and burst. The remaining process is the same as the previous one.

The duration of the action of the agents varies of course for different animals, depending upon their size and fineness—the most different Infusoria and Flagellata have been preserved in this way without manifesting the slightest shrinking. The cilia and vacuoles are quite life-like, and show the nucleus and nucleoli with an intense red colour. By far the best result, however, of the method is, the author considers, in its use for *Amœbæ*, the preserving of which had hitherto not succeeded. They are fixed in the position in which they are at the moment of the chromic acid being added. Even in the fine pseudopodia the vacuoles are easily to be recognized. The nuclei are also distinctly coloured.

In a postscript the author adds that Dr. A. Gruber, of the Freiburg Zoological Institute, who had previously found the process very useful for Rhizopoda and allied organisms, has since tried it on Heliozoa and found it to succeed excellently.

Preserving Protozoa.†—Referring to the preceding paper, B. Landsberg considers that it is a disadvantage that all the operations have to be performed under the cover-glass. It is scarcely possible, therefore, to prepare clean slides, as foreign bodies once under the cover-glass cannot be removed. It is also to be doubted whether the osmic acid can act with the necessary suddenness and in sufficient concentration, and finally there is the danger of the object swimming away.

He therefore proposes a method which obviates all these inconveniences, and which even a beginner can soon learn.

A small quantity of water being placed in a watch-glass or on a slide (without a cover-glass), is observed under the Microscope, and when an object is seen which it is desired to mount it is sucked up by a fine pointed capillary tube, taking care to have a little

* Arch. f. path. Anat. u. Physiol. (Virchow) lxxxiv.
† Zool. Anzeig., v. (1882) pp. 336-7.

water in the tube at first, so that the animal may not be destroyed by too strong a rush of water. The water is then emptied out of the tube into a drop of 1 per cent. osmic acid on another slide, and the acid allowed to act for about ten minutes as a maximum. The animal is then stained with Beale's carmine, washed with water, and after gradually hardening in alcohol transferred to oil of cloves.

Another process is to be recommended for small quick-swimming Protozoa. After it has been ascertained that the water in the watch-glass contains many Protozoa a sufficient quantity of osmic acid is poured in, and the subsequent processes of staining, washing, and transferring to alcohol and oil of cloves are all performed in the watch-glass. The animals are so fixed in the sediment that it is rarely any are lost in sucking off the fluid. Then a drop of the oil of cloves is taken up under the Microscope in a wider tube, and the organisms brought away isolated by the capillary tube and put at once into Canada balsam.

Although Canada balsam preparations have the advantage of greater durability, yet glycerine is to be preferred for many Protozoa. In particular, *Actinosphærium Eichhornii* is much more beautiful in glycerine than in Canada balsam. The frothy condition of the ecto-sarc is shown most clearly, and the contractile vacuoles remain, as in the living state, prominent at the surface of the animal.

Staining the Nucleus of Living Infusoria.—We are sorry that by the interpolation of the word " erroneously " at p. 281 it was made to appear that M. A. Certes was not justified in claiming as a " new fact " the staining of the nucleus of living Infusoria. The author of the interpolation, to whom we have referred on the subject, informs us that the fact of the note dealing with the *living* animals had momentarily escaped his attention.

Double Staining with Carmine and Anilin Green.*—Mr. T. W. Taylor obtains very beautiful results from the following method of using preparations of carmine and anilin green † together.

The section is immersed from five to ten minutes in the green, and then passed at once into the carmine, in which it remains from one to three minutes, the process being carefully watched in order that the carmine may not stain too deeply. It is then thoroughly washed in absolute alcohol, passed through oil of cloves, and then mounted in solution of balsam in benzole. The use of the benzole-balsam is important, as it has a decided action in fixing the stain, due to the presence of benzole. Two or three drops of each liquid suffice, and the whole operation is performed upon a glass slide, or in a watch-glass.

The woody parts of the section take a rich carmine, shading into orange, while the pith and light cellular tissue are stained a bright

† Carmine stain : carmine 15 gr., ammonia 15 gr., distilled water 2 oz.; dissolve carmine in ammonia over the flame of a spirit-lamp, add the distilled water and filter. Green stain : anilin green 5 gr., absolute alcohol 1 oz.

orange-yellow. In a section (transverse) of the leaf-stem of the sago-palm, the outer cells, which are smaller and more compact than the more central ones, were dyed a rich orange-yellow, and their nuclei a bright carmine. The curious large ducts in the central portion of the stem, which, as a system, form in a transverse section a figure like the Greek capital omega, take a pleasing variety of shades, the cells around the edges being a bright orange, the central cells shading down to deep carmine. These sections of the midrib of the sago-palm are beautiful objects stained or unstained, and one of the best examples of curious cell arrangements to be found anywhere.

The action of the dyes made from the above formula is quick and certain, and the effects very satisfactory.

Cutting Sections of Coal.[*]—Some discussion has taken place as to the feasibility of the method mentioned in the 'Micrographic Dictionary,' of macerating the coal in a solution of carbonate of potash, several authors finding that the coal still remained quite hard and impossible to cut. C. L. Lord finds the following method to be easy and successful when tried on the particular kind of coal mentioned by Huxley as containing macrospores and microspores in such abundance, viz. the Better-bed coal of Bradford and district. Grind a chip of coal to a smooth surface on an ordinary school-slate. Then cement it to a glass slide, either with shellac or Canada balsam. If balsam is used, it must be evaporated until it is of such hardness that a dent can only just be made in it by pressure with the thumb-nail, then remelt it and fix the smooth surface of the coal to the slide. The coal may then be ground on the slate to such a thinness as to show the spores. The coal-matrix containing the spores cannot be ground sufficiently thin to be transparent, and if it could be so ground, it is doubtful whether there would be any organic structure perceivable.

J. Walker selects from soft Iowa coal, some hard heads, so called (that is, hard lumps of coal in various stages of transition from good coal to charcoal), and well-preserved wood mixed with sulphide of iron. Breaking up these lumps and cutting out with a chisel the wood from the coal, which is the same as the coal without the bitumen, and breaking this in the proper direction, sections can be got both ways of the tissue, and when ground down thin make a good transparent object, or opaque with the condenser, when the sulphide of iron glistens like gold-dust among the woody tissue.

W. H. Harris has tried repeatedly to get a good slide of ordinary coal, and the outcome is one section only that shows any structure, and this was cut from ordinary marketable coal from Illinois, U.S.A. A piece of the coal was cut about a quarter of an inch in thickness with a fret saw, placed in pure turpentine for some considerable time, and then in dilute Canada balsam, until it was saturated. The turpentine was allowed to evaporate, and by a gentle application of heat the balsam the section had absorbed was gradually hardened. One side was then ground flat, polished and cemented to the slide;

when completed the other side was a simple repetition of careful grinding on a water-of-Ayr stone, just as an ordinary rock section would be treated, only with more care when the critical point was approached.

Finally, Dr. C. H. Griffith, one of the editors of the 'Micrographic Dictionary,' says he is "greatly amused at the discussion," and suspects the writers "have been experimenting with the refractory anthracite coal too common in our coal-scuttles; but this being nearly all mineral matter, of course, does not yield to the action of the potash. Neither would it show much if so cut. They remind me of a former sapient microscope pupil of mine, who took to himself much credit for soaking a nail from the 'Victory,' in the hope of making a section of it for the Microscope to show the structure. The coal for which this process is recommended, and which yields the best objects, is that which is more of a lignite character, and when so treated and digested with heat, is cut readily. To my own knowledge Professor Henfrey cut hundreds of sections in this manner."

Sections of Mica-schist.*—In a paper describing the methods he originally adopted for rock sections, Dr. H. C. Sorby says that it is possible to prepare thin sections of mica-schist perpendicular to the foliation, although it is so friable that at first sight it appears impossible. Having got a fairly thick portion and reduced it to about $\frac{1}{8}$ inch, it must be wetted well with turpentine so that it may penetrate into the pores of the rock, and then covered over with Canada balsam and kept hot inside the fender. The balsam penetrates into the loose material, and thus supplies artificially what nature has failed to supply in not having hardened it sufficiently by infiltered quartz. It is well to repeat the process after a little time.

By this means the weak points of the mica-schist and the planes of discontinuity are filled with hard Canada balsam so as to make it thoroughly hard throughout, and enable it to be rubbed down and the section left of the desired thickness.

Paper Cells.†—Mr. W. H. Walmsley, in an article (the third of a series) on Dry Mounting, considers that the remedy for the appearance of moisture in cells is to be found in "sacrificing artistic cells of wax, with their pretty coloured rings of varnish, and being content with those of humbler and far more useful qualities. Paper, from which such dissimilar articles are now manufactured as love-letters and car-wheels, is our friend in need in this emergency,—not sized, or glazed, or calendered, but soft, porous paper of various thicknesses to suit our needs; a thick blotting pad being exceedingly useful for cells containing objects sufficiently thick to require such a depth."

Wax Cells.‡—Mr. T. Whitelegge proposes "a very simple method of making wax cells. A piece of glass tubing is first drawn out to a point so as to form a pipette, and this is filled with melted

---

‡ North. Microscopist, ii. (1882) p. 194.

white wax. The slip upon which the cell is to be made is placed on the turntable, and while it is spinning, touched with the point of the wax pipette, previously heated so that the wax may flow out readily. A wax ring is thus made quite as easily as one of varnish, and if the ordinary pharmaceutical white wax be employed, it will adhere very tenaciously to the slide. It is obvious that many varieties of rings may be made by modifying the temperature of the wax or even by warming the slide, and as an operation of this kind generally requires some little practice in order to obtain the best results, a few failures at the outset should not discourage the operator from further attempts."

Miller's Caoutchouc Cement.—Mr. R. Miller, while not claiming to have discovered any new substance, has hit upon a new method of combination by which a material is obtained easy and quick to work and reliable in its results, and available both for making and sealing cells. It has stood a test of eighteen months.

The following are his directions for using it:—

To turn Cells. — Centre the glass slide on the turntable, and with a camel's-hair brush previously charged with sufficient cement, mark off the foundation of the cell in width and size required, the turntable being somewhat rapidly revolved; dip more cement and apply directly before the first layer can set, and so on, always touching the top of the stream only, until the cell be raised to the height desired, then lay the slide aside in a level position to dry. Slight cells dry in a few hours, deep cells, say $\frac{1}{8}$ of an inch, in two or three days. One hundred perfect cells may be turned in an hour by a beginner, and nearly twice that number by an adept. (Keep the brush clean and the bottle tightly corked.)

To mount in Glycerine, Oil, Canada Balsam, or other Fluids.— Take a cell perfectly dry, apply or turn a sufficient layer of the cement round the top of the cell, slightly overfill the cell with glycerine, and put in the prepared object, place on the glass cover (previously tested to fit), press down the centre and edges of the cover until it is firmly in position, and with a damp brush gently remove the expelled glycerine; test again by slight pressure that the cover is on the cement, and lay aside to set. A few hours afterwards the slide may be immersed in a basin of water and thoroughly cleansed with a camel's-hair brush, wash again if necessary, and when thoroughly freed from all traces of glycerine and quite dry, turn a layer of the cement over the cell embracing the rim of the glass cover, and finish to taste. The slide will then be found to be durably sealed and the fluid permanently confined.

These directions apply to mounting objects in oil or fluid Canada balsam, except the use of water to clean them; the superfluous oil or balsam must be removed by a brush dipped in benzole, the brush being continually wiped between a cloth. Do not use balsam diluted with ether or chloroform.

Mounting in Phosphorus.—The following is the note which Dr. Morris has written out, as mentioned, *post*, p. 591. It must,

however, be borne in mind that the sole advantage of phosphorus is its high refractive index = $2 \cdot 1$. If it is diluted to $1 \cdot 7$, no benefit is derived from its use over bisulphide of carbon or other substances whose refractive index = $1 \cdot 7$, and they should therefore be used in preference. Dr. Morris's note, however, contains some useful hints.

" Having seen several specimens of diatoms mounted in phosphorus and bisulphide of carbon, I am under the impression that the solution is too strong for the purpose required, and as I have mounted some hundreds of slides in the strong and weak solutions, I have come to the conclusion that the weak solution is the best and safest for mounting minute objects, such as the Diatomaceæ.

" The solution I use is made as follows :—Take one ounce of carbon bisulphide and put it into a wide-mouthed stoppered bottle, and add about two or three drachms of phosphorus piece by piece, taking the precaution to previously absorb all the moisture from its surface by placing it on blotting-paper for a second or two. When all is dissolved, filter through white filtering-paper and a glass funnel into another bottle (narrow-mouth stoppered), wash the filter with a little carbon bisulphide, and when filtered place the filter in a basin of water until there is time to burn it in the fire.

" Having made and filtered the solution, take a small piece of white blotting-paper about an inch square, and with a glass rod put a drop of the solution on the paper and watch the effect. If it flares up with a yellow flame it is too strong, and requires more carbon bisulphide added to it, but if it only smokes and carbonizes the paper the solution is of the right strength. See that the stopper is well fixed in the bottle, and put it away for a day or two. If any sediment has formed in the meantime, filter once more, using the same precautions with the filter as before.

" If the solution is made according to the above directions, it will be always ready for use and keep for months.

" To make cement for the cover-glass, take of good isinglass one ounce, put it into a saucer, add a few drops of water from time to time until the isinglass is moistened but not pappy. Put about two ounces of glacial acetic acid into a porcelain capsule, place it over a spirit-lamp, and bring the acetic acid to boiling-point. Add the isinglass by degrees until the whole is dissolved, keeping the mixture constantly stirred. Boil until a spot placed upon a slip of glass becomes solidified when cold. When sufficiently boiled, put it away in a wide-mouthed bottle, using a cork for a stopper. A small quantity for constant use may be kept in a two-drachm bottle. This must always be warmed in hot water before applying it.

" The diatoms being fixed on the cover, see that the following articles are at hand :—A small bottle of carbon bisulphide, a glass pipette four inches in length terminating in a fine point, a few pieces of blotting-paper one inch by half an inch, small camel-hair brush, mounted needles, a small basin, and a turntable.

" First gently warm the slide, centre it on the turntable, warm the cover-glass and place it on the slide, wash the pipette with the carbon bisulphide, then with the pipette take up a small quantity of

the solution of phosphorus and allow it to run under the cover just sufficient to float it. See that there are no air-cells, if so, gently move the cover backwards and forwards to the mounted needles, when all the air-cells will disappear. Take the small brush, load it with the warmed cement, and touch the edge of the cover-glass at right angles in four places, then gently revolve the turntable, keeping the brush close to the edge of the cover until the cement ring is complete, then absorb the remainder of the phosphorus solution on the slide with the strips of blotting-paper, putting the paper into the basin of water so that it can do no harm. As long as the blotting-paper saturated with a solution of phosphorus is wet, no combustion will ensue. Hence the necessity of seeing that all which has touched the solution of phosphorus has either undergone combustion or been placed in the fire before leaving off work.

" The mounted slide may be again touched with the cement, when it can be put away until the following day. A ring of solution of sealing-wax or shellac may then be used to finish it off. If by accident more of the cement has got on the slide than is required, when the ring of sealing-wax is hard, the cement can be washed off with a small brush dipped in water and applied gently. When dry it can then be finished off as the mounter may fancy.

" Always wash the pipette in the carbon bisulphide before and after using the solution of phosphorus. Latterly I have discarded the soft cell and always mount as described, because I found that the solution of phosphorus is very liable to form air-cells; or, in other words, there is a want of affinity between the glass and the medium, and if it is a valuable preparation it may be completely spoiled on account of the air-cells; whereas by doing away with the soft cell and mounting as I have described, the air-cells can always be got rid of before applying the ring of cement.

" Diatoms are easily resolved in this medium, which in a dry or balsam mount are unresolvable."

Vacuum-bubbles in Canada Balsam.*—Mr. W. M. Bale says, " One of the first difficulties which a novice in mounting meets with arises from the formation of air-bubbles in Canada balsam, but experience shows him that if the balsam be used in not too thick a state, any bubbles that may form in it will, unless they are excessively large, gradually disappear in the course of a few days at most, and henceforth air-bubbles in the balsam cease to be a source of trouble.

It is otherwise, however, with vacuum-bubbles, which are apt to appear in any closed cavities of an object at the moment of applying the balsam, even though every cell may have previously been perfectly filled with turpentine or carbolic acid. The cause appears to lie in the different densities of the fluid and the balsam, the former finding its way out of the cell to mix with the balsam, while the latter, owing to its greater density, is unable to enter the cell and supply its place. A vacuum is therefore left, which has all the appearance of an air-bubble, and which may either take a globular form or expand till it

---

* Journ. Micr. Soc. Victoria, i. (1882) pp. 103–4.

completely fills the cell. In the former case it is evident that the balsam is finding its way into the cell, though slowly, and if it is thin enough to retain its soft condition for a few days, the bubbles will probably disappear ; but when they completely fill the cell it is a sign that the balsam cannot find entrance, and the object can then only be cleared by again soaking it in the fluid solvent. Among the objects most liable to this inconvenience may be mentioned sections of some wood, also such Bryozoa as some of the common *Catenicellœ*, the avicularian processes of which usually contain perfectly closed-in chambers. In the closed gonothecæ of some of the most delicate hydroids the same cause is followed by different results—the escape of the fluid and the inability of the balsam to enter, causing the collapse of the thin chitinous investment, instead of the formation of a vacuum-bubble, as is the case where the wall of the closed cavity is strong enough to resist the pressure of the balsam. Precisely the same phenomenon is observed when delicate vegetable tissues are placed in glycerine, and the means used to prevent it, viz. thickening the medium very gradually, suggested to me the idea of applying the same principle to balsam mounts.

An easy method of doing this is to place the object in turpentine on the slide under a large cover-glass, and with a glass-rod, deposit round the margin an embankment of soft balsam, then lay the slide aside till the balsam and turpentine are thoroughly mixed, which will be a slow and gradual process. It is not advisable to use carbolic acid for this work, at least if there be any considerable depth between the cover and the slide, as the mixture of acid and balsam assumes a rather deep colour. A slight modification of this plan may be used with advantage to prevent delay in the drying of the slide, as follows : —Place the object (saturated with carbolic acid) in the middle of the slide, and make a little embankment of balsam at some distance all round it, then fill the space within the balsam with a pool of the acid, and place the slide under the cover till the acid and the balsam are sufficiently mixed (ten minutes or a quarter of an hour), then drop fresh balsam on the object and cover as usual. Turpentine is not suitable for this purpose, as it runs all over the slide."

Mounting Moist Objects in Balsam.*—Dr. Johnson (of Victoria) some years ago recommended as a means to mount Sertularians, Bryozoa, &c., that the objects should be boiled in water till all the air is removed, then drained, placed for a few hours in carbolic acid, and thence transferred to the slide and mounted in balsam. It will be found, however, writes Mr. W. M. Bale, " that the water contained in the interior of the specimens being taken up by the acid will, unless a large quantity of the latter be employed, or the objects be placed in two successive baths of it, be sufficient to cause a cloudiness in the balsam. Moreover, it is frequently undesirable to lose time by putting the object aside till the water and acid have completely mixed ; and to remedy these inconveniences, the object, after removal from the water, should be placed in methylated spirit, which will

* Journ. Micr. Soc. Victoria, i. (1882) pp. 104–5.

take the place of the water in a very few minutes, thence it may be transferred to carbolic acid and boiled in it for fifteen or twenty seconds, when the object will be ready for mounting at once. I use this method for all moist specimens, and find it of great advantage in enabling me to mount them without delay, besides which, the quantity of acid used or spoiled is comparatively small, its place being partially filled by the inexpensive methylated spirit."

Moisture in Dry Mounts.[*]—Mr. W. M. Bale adopts the following very simple plan of mounting objects to allow of the circulation of air through the cell. Take an ebonite cell, and if necessary trim the edge neatly with a file, then with a file or knife cut two opposite broad, shallow notches on that side of the cell which is to be underneath ; then cement the cell to the slide, taking care not to allow the cement to fill the notches, which, being shallow, are quite unnoticed unless looked for. The object may be placed in the cell, and the cover cemented on at leisure. If a bright edge be required to the cell, it is only necessary to paint it with a thin solution of balsam or dammar, and no varnish ring on the cell is requisite (unless some other colour than black be desired), as the ebonite cell supplies in itself a sufficiently neat finish. Those who are in the habit of using the excellent slides made by glueing perforated wooden slips to strips of card, can easily provide for the circulation of air by making one or two small slits in the card bottom of the cell.

To obtain the freest circulation of air through the cells it will be advisable to leave the slides in an open rack box till the cement is hardened, rather than to close them up at once in a cabinet.

Dammar Varnish.[†]—This being, according to W. Pfitzner, preferable to Canada balsam, he prepares the solution in the following way :—Gum dammar, benzine, and turpentine, are mixed in equal parts, and put in a warm place. As soon as complete solution has taken place, the clear liquid is poured off, and allowed to evaporate until of the required consistency. Dr. M. Flesch [‡] adds that in Würzburg, dammar varnish, as used by painters, is generally employed.

Cleaning Used Slides and Covers. [§] — Mr. F. Barnard recommends the warming of the slide over a spirit-lamp and removing the cover, which is at once to be dropped into a bottle containing methylated spirit of wine, to which has been added 25 per cent. of liquor potassæ. Then scrape off as much balsam as possible with an old knife, and with a rag wetted with the above mixture clean the slide. Afterwards, a second rag wetted with the same liquid is used if necessary ; and *while wet*, the slides are dropped into a basin of water. It will then only be necessary to thoroughly wipe them with a clean cloth. Breathing on them will show at once whether they are clean or not.

  * Journ. Micr. Soc. Victoria, i. (1882) pp. 101–3.
  † Morphol. Jahrb., vi. (1880) p. 469.
  ‡ Zool. Jahresber. Neapel for 1880, p. 51.
  § Journ. Micr. Soc. Victoria, i. (1882) pp. 106–7.

While the slides are cleaning, the cover-glasses should be soaking in spirit and potash. They may now be removed one by one, and wiped on a rag. If necessary, they can be so treated a second time; but in either case they are to be dropped while wet into clean water. In removing the covers it will be found that the spirit and potash has decomposed the balsam and any gold-size, black varnish, &c., upon them, and the dropping them while wet into the water prevents the adherence of any particles by the decomposition caused by it.

Mr. Barnard has tried benzine, turpentine, and many other things, but nothing seems so expeditious and cleanly as the mixture recommended, as it frees the slide from grease, which has to be done after using benzine or turpentine. There is a risk in leaving the covers in the bottle of spirit and potash too long, for fear of an injurious effect of the potash on the glass; but this has not yet happened, though they have been left uncleaned for a long time after being removed from the slides.

Resolution of Amphipleura pellucida. — Mr. E. M. Nelson informs us that since the date of the December conversazione of the Society he has found that the exhibit he then made of *longitudinal* lines on *Amphipleura pellucida* (dry on cover-glass) was an error—the lines then shown were due to diffraction. He has since observed true longitudinal lines on this diatom by a more careful adjustment of the vertical illuminator, and has assured himself that they are finer than the 10th band of Nobert's latest 20-band plate, i. e. finer than 112,595 to the inch. The objective was Powell and Lealand's $\frac{1}{12}$ homog. imm. of 1·43 N.A.

Repeated countings of the *transverse* lines on the particular frustule examined show them to be at the rate of 96 in the ·001 inch, and therefore capable of resolution by any immersion objective (of sufficient power) whose effective aperture exceeds 1·0 N.A., and conversely incapable of resolution by any dry lens.

Microscopic Examination of Wheat-flour.[*]—C. Steenbuch recommends the following mode of preparing meal for microscopic examination and determination of the starch-grains, by which the elements of the tissue can be easily isolated. The process depends on the well-known fact that a solution of diastase transforms starch-paste into dextrin and maltose. In order to obtain a solution of diastase, 20 g. of ground meal are placed for an hour in 200 g. cold water and repeatedly shaken, and then filtered through a double filter. 10 g. of the specimen of meal to be examined are then thoroughly mixed with 30–40 g. of cold water, the mixture placed in a beaker, and stirred up with about 150 g. of boiling distilled water. At a temperature of 75°–80° C. the formation of paste begins. The temperature is now allowed to fall to 55°–60° C., and 30 c.cm. of the clear filtered extract of malt added. The mixture is then stirred up, and the temperature kept at 55°–60° in a water-bath for 10 minutes.

* Ber. deutsch. chem. Ges., xiv. (1881). See Bot. Centralbl., x. (1882) p. 140.

Destruction of Microscopical Organisms in Potable Water.[*] —Langfeldt, in seeking for a substance which would kill the living organisms without injuring the water for drinking purposes, found that citric acid ($\frac{1}{2}$ gram per litre of the water) killed all except *Cyclops* and those with thick epidermis, within two minutes.

Public Lectures in Microscopy.[†]—In October last the French Minister of Agriculture and Commerce instituted a gratuitous course of instruction in micrography at the " Ecole Supérieure de Pharmacie " at Paris, intended for theoretical and practical instruction in the functions of microscopical experts.

PROCEEDINGS OF THE SOCIETY.

MEETING OF 14TH JUNE, 1882, AT KING'S COLLEGE, STRAND, W.C., THE PRESIDENT (PROFESSOR P. MARTIN DUNCAN, F.R.S.) IN THE CHAIR.

The Minutes of the Meeting of 10th May last were read and confirmed, and were signed by the President.

The List of Donations (exclusive of exchanges and reprints) received since the last meeting was submitted, and the thanks of the Society given to the donors.

	From
Cole, A. C.—Studies in Microscopical Science, Vol. i. Nos. 1 and 2, and two preparations in illustration	*The Editor.*
Geological Magazine, Vols. i.–xviii. (1864–81)	*Mr. Crisp.*

Micrographic Dictionary. 4th ed. Part 12	*Mr. Van Voorst.*

The President called special attention to the donation of a complete set of the 'Geological Magazine,' and Mr. Stewart referred to the 'Studies in Microscopical Science,' edited by Mr. A. C. Cole, the illustrations of which he considered were very good, and the letterpress appeared to be equally so. The novel feature was that a microscopical preparation accompanied each part.

Mr. Crisp exhibited a ¼-inch objective by Tolles, with a very tapering front, and stated that it was claimed on Mr. Tolles' behalf that he was the first to make such fronts about ten years ago.

Mr. Ingpen said that he had one of Andrew Ross's ½-inch objectives with a triplet front, dated 1848, which was similarly tapered.

Mr. Beck said that he had made them in the same way for the last fifteen years.

The President, referring to J. L. de Lanessan's 'Traité de Zoologie—Protozoaires' (8vo, Paris, 1882, pp. vii. and 336, and 281 figs.), said that it treated of *Amœbæ* on a somewhat grand scale, particularly as regarded the larger kinds, and he would suggest to some of the Fellows that they should search for these species as being of great interest. He obtained one from the Hampstead ponds which he found full of minute refractile points.

Mr. Stewart said he had examined some large *Amœbæ*, a short time ago, which came from Mr. Ingpen's aquarium, and were crowded with refractile points. They were distinctly crystalline in character, and had a vesicular nucleus.

Mr. Hartog said that he used to find the nuclei in the large Amœbæ with a very distinct network, although one which he found had a hollow nucleus.

The President inquired if Mr. Hartog had ever been able to iodize Amœbæ?

Mr. Hartog said he had stained them with picro-carmine, but had not done so with iodine.

Dr. Ralph, the President of the Victoria (Australia) Microscopical Society, responding to a welcome from the President and the Meeting, said he should like to take the opportunity of bringing before the Fellows of the Society the examination of the leaves of various kinds of plants by means of the action of prussic acid and ammonia. The process was a very simple one, it being only necessary to place the section under the Microscope, and then introduce the compound. He had only had time as yet to examine a few kinds of leaves in this way, but the vine had hitherto given the most marked instances of the chemical action to which he referred. A longitudinal section as thin as possible being made of the leaf and placed under the Microscope, the fluid should be added, and would be found to penetrate the structure, chiefly acting on the ducts, which were within reach of the bark. In a few moments the most extraordinary colours made their appearance, such as claret, amber, port-wine colour, and others having all the appearance of a coloured injection of the tissue, only that in about a quarter of an hour it all disappeared. Other leaves which he had tried behaved much in the same way, though they did not all respond to the reagent in an equal degree. It was only in the brittle sappy stems that it was possible to get the best results. In consequence of these observations, he had been able to treat sections of the human subject with prussic acid with marked effects. Whenever he got in the plasma amorphous particles distinctly blue in colour, he also found the formation of amyloid bodies in the blood. These bodies were very well defined, and under favourable circumstances, in polarized light, the black cross could be seen. The production of amyloid forms by chemical means, not only under the action of hydrocyanic acid, but by chloral, formic acid, or solution of copper in ammonia, was a point of considerable interest. If a portion of either of these reagents were added to fresh blood, and examined carefully under the Microscope, they would, in all probability, find these starch-like bodies developed in the field. It was not easy to show the process in a room to a number of persons; but if any one present was interested in these subjects, he should be very glad to demonstrate what he had been describing.

Mr. Stewart inquired whether these bodies were supposed to be formed by the reagent, or were they supposed to be really present before, but only to be made visible by the reaction?

Dr. Ralph said that under favourable circumstances they might see a globule which they would be disposed to say was oil; when the reagent was added it would increase in size from about the $\frac{1}{3000}$ inch to about the $\frac{1}{1000}$ inch; later it would suddenly become

opaque, and then it would colour in such a way that any one looking at it would say at once that it was starch. So far as he had carried out the observations, it seemed as if these starch-grains really did develope, and he thought it might be an instance of the commencement of the process of amyloid deposit.

Dr. Morris, of Sydney, was introduced to the Meeting by the President, and detailed some experiments which he had made in mounting diatoms in phosphorus in such a way as not to be inflammable. As he had only just arrived from Sydney, he had not had time to write anything on the subject.* He had seen some of the specimens which had been mounted in England, and was under the impression that the solution was too strong. He proposed, therefore, to reduce it to such a strength that if a piece of white blotting-paper was put into it, it would not blaze up. By such a solution all difficulty as to using the medium was done away with, the only necessary precaution being to have a basin of water near at hand to dip the fingers into.

Mr. Stephenson said that if they used a weak solution they would get a lower refractive index, whereas the principal object in mounting in phosphorus was to get as great a difference as possible between the refractive index of the medium and that of the object, for on this difference alone the increase of visibility depended.

Mr. Crisp said that if phosphorus was used diluted to a refractive index of $1\cdot7$, the visibility of the diatom would be proportionately reduced, and as there was no virtue in phosphorus, except for its high refractive index, it would be better not to use it at all in such a condition, but to take some non-inflammable substance which had the lower refractive index.

Dr. Morris said that, with regard to the value of the process, he might mention that he had tried some *Naviculæ*, and that with an oil-immersion lens the object mounted in phosphorus was resolved in the most perfect manner—far superior to anything that could be seen with balsam.

Mr. Crisp said that it must be borne in mind that the danger incidental to the use of phosphorus was not confined to the process of mounting. A case recently occurred in which an object-glass, brought down too hard, broke the cover-glass, and the observer, having wiped off the exuding phosphorus with his handkerchief, put it into his pocket and set himself on fire.

Mr. Ingpen exhibited and described some high-power achromatic eye-pieces, by Steinheil, of Munich (Series A F). They were constructed for astronomical purposes, but he thought they would prove serviceable for use with the Microscope. Those exhibited were of $\frac{3}{4}$, $\frac{1}{2}$, and $\frac{1}{3}$ inch focus, each having a field of $40°$ (see p. 551). Mr. Ingpen said that, whatever differences of opinion there might be as to

---

* See note by Dr. Morris written after the meeting, *supra*, p. 579.

the value of deep eye-pieces, there was probably none as regarded the desirability of securing the best possible definition, whatever amplification was used. He considered that with Huyghenian eye-pieces of less than an inch focus there was a serious deterioration of the image. The eye-pieces now exhibited gave the sharpest definition of any of similar foci he had hitherto been able to examine.

Mr. Crisp explained the new method devised by Dr. Ehrlich, the assistant of Dr. Koch, for preparing the bacteria of tuberculosis, which constituted a considerable improvement upon the original process. It produces a more intense colour in the bacteria, so that they appear larger, and can be recognized with a lower power, even, it is said, of 250 diameters (see p. 572).

Prof. Abbe's process of increasing the consistency of pure cedar-oil, so as to render it less fluid and therefore more convenient for use as a homogeneous-immersion fluid, was explained by Mr. Crisp. The oil is spread out in thin layers, and exposed to the action of the air and light for a long time, until it becomes of the consistency of castor-oil (see p. 551).

Mr. W. F. Petterd's letter was read accompanying a collection of diatoms from Tasmania.

Mr. A. Certes' letter, reiterating his claim to the discovery of a method of staining the nucleus of *living* Infusoria, was read by Mr. Crisp, who said that the author of the interpolation by which such a claim was described as "erroneous," now agreed that he was mistaken in the view he had expressed, not having in fact sufficiently noticed that the claim related essentially to the nucleus of the *living* animals (see p. 576).

Mr. Crisp called attention to a process devised by E. Korschelt, of Freiburg, for preserving Infusoria and *Amœbœ* by the use principally of osmic acid and chromic acid, no method having hitherto been found for the latter organisms. Dr. A. Gruber had also succeeded in preserving Heliozoa by the method, in excellent condition (see p. 574).

Mr. R. Miller's description of his caoutchouc cement for making and sealing cells was read, in which he stated that he did not claim to have discovered any new material, but to have accidentally hit upon a new method of combination. The material so obtained was singularly easy to work, and reliable in its results (see p. 579).

Dr. Van Heurck's letter was read describing favourably his further experiences with the Swan electric lamps and Faure-Reynier accumulators (see p. 557).

Professor **Abbe's** note was read with reference to the description of his camera lucida, *ante*, p. 261, in which he stated that the benefit of the arrangement consisted simply in the ease with which it may be used. In other respects it did not possess any advantage over those forms which fulfil the condition that the image is seen without reflection or other loss of light.

Mr. **Ahrens** exhibited and explained the construction of his new erecting binocular Microscope. In general outline it presented much the same appearance as that of Mr. Stephenson, the tubes being inclined, whilst the stage was horizontal. The erection of the image was, however, obtained by introducing a Nachet erecting prism over the objective, another prism similar to the Wenham being used above to divide the pencils.

Dr. **Millar** said that, whilst he could speak with great praise of the advantages of the erecting binocular as an instrument to work with, leaving nothing to be desired for comfort and convenience, he thought the one now before them did not appear to give an entirely satisfactory stereoscopic effect.

Mr. **Michael** said there was no doubt that a binocular Microscope, with a flat stage and an erecting arrangement like that of Mr. Stephenson, was an immense help to those who worked at living objects. In drawing from living insects he had found it of the greatest practical service.

Professor **Liversidge's** communication on the "silver-fish" of Sydney was read, in which he defended the accuracy of the observations of Hooke recorded in his 'Micrographia' (1665) as against the strictures of Mr. W. Blades in his 'Enemies of Books' (3rd edition, 1881). Specimens of the insects were sent, and labels and sheets of paper destroyed by them exhibited (see p. 500).

Mr. **Hartog** said there was no doubt as to the animal being *Lepisma saccharina*, the same that was often found in this country. It was mentioned by Emerson Tennant as being thought by some to prey upon books, but the author was of opinion that it rather preyed upon the insects which were found in the books, a view which he (Mr. Hartog) considered an error.

Mr. **Thom's** letter on *Saccharomyces* was read, in which he mentioned that he had devoted all his spare time for ten years in tracking these organisms, and now made all his bread without any yeast, so called.

Mr. **Bennett**, to whom the letter was addressed, made some remarks upon the subject.

Mr. **Badcock's** note was read (in his absence from illness) as to his observation of eyes in the adult forms of *Melicerta ringens*, *M. tyro* (or *tubicularia*), and *Stephanoceros Eichhornii*, also as to the development of the latter form from the egg. He also pointed out that

the tube with advancing age got filled up with mucilage, until only just room enough was left for the creature to move up and down (see pp. 345-6 and p. 512).

Mr. Badcock's note was read as to a criticism by Professor O. Bütschli of his paper on Acinetina (this Journal, III. (1880) p. 561), which had appeared in the 'Zoologischer Jahresbericht' for 1880 (p. 173). Professor Bütschli, in remarking on Mr. Badcock's comparison of the finely ciliated newly-born *Podophrya quadripartita* to *Megatricha partita*, referred to the latter as a Rotifer (!), being apparently surprised that such a comparison should have been made. At first Mr. Badcock was puzzled to know how the reporter could have fallen into such a mistake, but it had since occurred to him that the explanation was to be found in the fact that there were Rotifers named *Megalotricha*, and although these were very large Rotifers, while *Megatricha* is one of the most delicate of all the Ciliata, it was most probable that this was the origin of the mistake.

Mr. Wilson thought it was strange that Professor Bütschli, who was a very eminent authority on the Protozoa, should not have been familiar with *Megatricha*, as appeared to be the case. Many of the reviews in the 'Zoologischer Jahresbericht' were, however, obliged to be hastily done, and some excuse must be made on that account, as well as for the fact that the reporters had to deal largely with papers written in foreign languages.

Professor Abbe's paper " On the Relation of Aperture to Power," Part II., was laid before the meeting by Mr. Crisp, who said that as it was a very long communication, he had prepared a *résumé*, which presented the leading points in a condensed form suitable for being read to the Meeting. This he was proceeding to do, when

Mr. Beck, interposing, said he thought that as the paper was an important one, and required a good deal of consideration, a *résumé* of it would be of very little use to them. He would suggest, therefore, that the paper should be printed, and that when it had been before them *in extenso*, an evening should be specially devoted to its consideration and discussion.

The Chairman (Mr. Glaisher, in the absence of the President), on the contrary, thought that it would be very useful to have an abstract of the paper read.

Mr. J. Mayall, jun., also thought it very desirable that the Society should be in possession of Professor Abbe's views, without having to wait until the next issue of the Journal.

The Meeting having indorsed this view, Mr. Crisp read a *résumé* of the paper (see p. 460).

The Chairman said that the paper was obviously one of very considerable importance, and he had great pleasure in proposing that the warm thanks of the Society should be presented to Professor Abbe for it.

Mr. Stephenson seconded the suggestion, and said that, having

had the advantage of reading the paper in MS., he was able to say that it contained a most exhaustive discussion of the subject.

Mr. Crisp said that it was the first attempt that had been made to establish a definite relation between aperture and power, and amongst other benefits it could not fail to prevent the perpetration in future of such absurdities as had been issued in the way of low-power objectives with very large aperture.

The Chairman said that the report of the committee appointed to consider the question of standard gauges for eye-pieces and substages had been adopted by the Council. The gauges recommended for eye-pieces were 1·35 inch and 0·92 inch, and for substages 1·5 inch.

The following is the report of the committee :—

" The committee who were appointed under a resolution of the Council directing them to ' consider the advisability of establishing standard gauges for eye-pieces and substages,' after communication with the leading opticians and with Fellows of the Society, now present their report as follows :—

" The committee have found that a very general desire exists on the part of workers with the Microscope that there should be *standard gauges* both for eye-pieces and substages, and the committee therefore resolved ' That in the opinion of this committee it is expedient that standard gauges should be established for the eye-pieces and substages of Microscopes.'

" In considering the question of the *number* of standards to be adopted, the committee were of opinion that it would not be practicable to establish a single uniform gauge for eye-pieces. On the one hand, a considerable number of Microscopes issued are of small size, and could not with convenience be fitted with a body-tube of large diameter ; while, on the other hand, it would be undesirable to reduce the diameter in use with first-class instruments. The same considerations do not apply to the case of substages, which are frequently of as great a diameter in the smaller instruments as in the larger. The committee, therefore, resolved to recommend ' That the standards for eye-pieces should be two in number, with a single standard for substages.'

" With regard to the *size* of the standards, the committee did not feel themselves able to treat the question as one entirely open, but considered that it would be preferable to select some sizes already in general use, so as to involve the minimum of change. They therefore resolved to recommend ' That the two standard gauges for eye-pieces should be, for the No. 1, 1·35 inch, and for the No. 2, ·92 inch (external diameter), and that the gauge for the substages should be 1·5 inch (internal diameter).' The No. 1 gauge is generally used for the larger instruments in England, whilst No. 2 is that adopted by many Continental makers."

Mr. Crisp said that it should be mentioned that there had been some difference of opinion, both on the part of the committee and the Council, as to whether there should not be a third intermediate

gauge; also, that in selecting the sizes mentioned by the Chairman, regard had been had to those which were at present in most frequent use, so as not to disturb existing arrangements more than could be helped.

The following Papers were taken as read :—

" Plant Crystals," by Dr. Aser Poli, of Rome.

" Note on the Rev. G. L. Mills' Paper on Diatoms in Peruvian Guano," by Mr. F. Kitton.

" On the Estimation of Aperture in the Microscope," by the late Mr. Charles Hockin, jun.

The following Instruments, Objects, &c., were exhibited :—

Mr. Ahrens :—New Erecting Binocular Microscope.

Mr. Bolton :—Spawn of Perch.

Mr. Crisp :—(1) Balkwill's Slide of Foraminifera. (2) Hardy's Compressorium (see p. 553). (3) Malassez's Compte-Globules (see p. 559). (4) Tolles' $\frac{1}{4}$-inch objective with very tapering front. (5) Tolles' Camera Lucida (see Vol. III. p. 527).

Mr. Ingpen :—Steinheil's High-power Achromatic Eye-pieces, $\frac{3}{4}$-inch, $\frac{1}{2}$-inch, and $\frac{1}{3}$-inch.

Prof. Liversidge :—" Silver-Fish " (*Lepisma*) from Sydney, N. S. Wales.

Mr. R. Miller :—Caoutchouc Cement.

Dr. Ralph :—*Vallisneria* from Melbourne.

Dr. G. M. Sternberg :—Photographs of Bacteria (see p. 571).

New Fellows.—The following were elected *Ordinary* Fellows :—Messrs. William Borrer, jun., William E. Pickels, John Rookledge, Thomas C. Squance, M.B. and M.S., and Prof. Albert H. Tuttle, M.Sc. (At p. 443 for Henry Pocklington read Christopher Pocklington.)

COUNCIL.

ELECTED 8th FEBRUARY, 1882.

PRESIDENT.

PROF. P. MARTIN DUNCAN, M.B., F.R.S.

VICE-PRESIDENTS.

ROBERT BRAITHWAITE, Esq., M.D., M.R.C.S., F.L.S.
ROBERT HUDSON, Esq., F.R.S., F.L.S.
JOHN WARE STEPHENSON, Esq., F.R.A.S.

TREASURER.

LIONEL S. BEALE, Esq., M.B., F.R.C.P., F.R.S.

SECRETARIES.

CHARLES STEWART, Esq., M.R.C.S., F.L.S.
FRANK CRISP, Esq., LL.B., B.A., V.P. & TREAS. L.S.

Twelve other MEMBERS of COUNCIL.

LUDWIG DREYFUS, Esq.
CHARLES JAMES FOX, Esq.
JAMES GLAISHER, Esq., F.R.S., F.R.A.S.
J. WILLIAM GROVES, Esq.
A. DE SOUZA GUIMARAENS, Esq.
JOHN E. INGPEN, Esq.
JOHN MAYALL, Esq., Jun.
ALBERT D. MICHAEL, Esq., F.L.S.
JOHN MILLAR, Esq., L.R.C.P.Edin., F.L.S.
WILLIAM THOMAS SUFFOLK, Esq.
FREDERICK H. WARD, Esq., M.R.C.S.
T. CHARTERS WHITE, Esq., M.R.C.S., F.L.S.

I. Numerical Aperture Table.

The " APERTURE " of an optical instrument indicates its greater or less capacity for receiving rays from the object and transmitting them to the image, and the aperture of a Microscope objective is therefore determined by the ratio between its focal length and the diameter of the emergent pencil at the plane of its emergence—that is, the utilized diameter of a single-lens objective or of the back lens of a compound objective.

This ratio is expressed for all media and in all cases by $n \sin u$, n being the refractive index of the medium and u the semi-angle of aperture. The value of $n \sin u$ for any particular case is the "*numerical aperture*" of the objective.

Diameters of the Back Lenses of various Dry and Immersion Objectives of the same Power (¼ in.) from 0·50 to 1·52 N. A.	Numerical Aperture. ($n \sin u = a$.)	Angle of Aperture ($= 2u$.)			Illuminating Power. (a^2.)	Theoretical Resolving Power, in Lines to an Inch. ($\lambda = 0\cdot5269\,\mu$ = line E.)	Penetrating Power. ($\frac{1}{a}$)
		Dry Objectives. ($n = 1$.)	Water-Immersion Objectives. ($n = 1\cdot33$.)	Homogeneous-Immersion Objectives. ($n = 1\cdot52$.)

EXAMPLE.—The apertures of four objectives, two of which are dry, one water-immersion, and one oil-immersion, would be compared on the *angular* aperture view as follows:—106° (air), 157° (air), 142° (water), 130° (oil). Their actual apertures are, however, as   ·80   ·98   1·26   1·33   or their numerical apertures.

W. EMIL BOECKER,

MANUFACTURING OPTICIAN,

WETZLAR, GERMANY,

SENDS GRATIS HIS CATALOGUE

OF MICROSCOPES, OBJECTIVES, MICROTOMES, AND APPARATUS
FOR SCIENTIFIC RESEARCH.

Heinr. Boecker's Microscopical Institute, at Wetzlar, Germany,
SUPPLIES
MICROSCOPICAL PREPARATIONS

In all branches of Natural History. A Large Selection of Injections, Stained Preparations, Insects, Crustacea, Entozoa, and Lower Animals; Vegetable Anatomy, Woods, Articles of Food, Algæ, Mosses, Fungi, Diatoms, and Sections of Rocks and Fossils. Instruments and Appliances for Mounting, &c. Sciopticon, with addition for using microscopic objectives. Glass Photograms.
Catalogue No. IX., Gratis and Post-free.

Just Published, price 1s. 1½d. post-free, Part 3.

THE JOURNAL OF THE POSTAL MICROSCOPICAL SOCIETY.

CONTENTS.

On the Embryology of the Podophthalmata, or Stalk-eyed Crustacea — The Adulteration of Coffee and the Microscope (*Plate*) — A New Growing-Slide (*Illus.*) — Spiders; their Structure and Habits. Part 2 (*Plate*) — Unpressed Mounting for the Microscope — Aquaria for Microscopic Life — How to Prepare Foraminifera (*Illus.*) — An Hour at the Microscope with Mr. Tuffen West (2 *Plates*) — Selections from the Society's Note-Books (*Plate*) — Reviews — Correspondence (*Illus.*) — Notices to Correspondents, &c., &c.

W. P. COLLINS, 158, Great Portland Street, London, W.

THE "SOCIETY" STANDARD SCREW.

The Council have made arrangements for a further supply of Gauges and Screw-tools for the "SOCIETY" STANDARD SCREW for OBJECTIVES.

The price of the set (consisting of Gauge and pair of Screw-tools) is 12s. 6d. (post free 12s. 10d.). Applications for sets should be made to the Assistant-Secretary.

For an explanation of the intended use of the gauge, see Journal of the Society, I. (1881) pp. 548–9.

ADVERTISEMENTS FOR THE JOURNAL.

Mr. CHARLES BLENCOWE, of 75, Chancery Lane, W.C., is the authorized Agent and Collector for Advertising Accounts on behalf of the Society.

Plant Crystals

TRANSACTIONS OF THE SOCIETY.

XIV.—*Plant-Crystals.* By Dr. ASER POLI.

(*Read* 14*th June*, 1882.)

PLATE VI.

PLANT-CRYSTALS were first observed by Malpighi,* and afterwards
by all phytotomists. But the earliest researches on their composition
and anatomical distribution in many plants were made by Sanio
(1857). Gulliver has also published, from 1859 to 1880, several
papers on plant-crystals, and especially on their classificatory signifi-
cance, but I am sorry to have found his works very little known,
although they contain a great many very important observations.
Holzner ('Flora,' 1864–69) studied the chemical composition, the
crystalline shapes, and physiological significance of plant-crystals;
and the other authors who have dealt with the subject are quoted
in my work 'I cristalli di ossalato calcico nelle piante,' Roma,
1882.

I. *The Composition of Plant-crystals.*—We may say that
almost all plant-crystals are of calcium oxalate. There are
crystals of calcium phosphate and tartrate, of potassium oxalate,

&c., but they are distinguished by their solubility in water, or in acetic acid. All plant-crystals which are insoluble in water and acetic acid, and soluble in mineral acids, are composed of calcium oxalate.

There are no crystals of calcium carbonate or sulphate in plants.*

Holzner has given a table for distinguishing the crystalline formations in plants by chemical reactions.†

II. *Crystalline form of Calcium oxalate.*—Calcium oxalate crystallizes in the tetragonal system, with three molecules of water ; in the monoclinic system, with one molecule of crystallization water. The octahedrons are generally tetragonal (e. g. crystals of *Begonia, Tradescantia,* &c.); the short prismatic crystals, the raphides, and all those crystals which were believed to be of sulphate of calcium (e. g. the long prismatic crystals of *Iris*), are monoclinic.

III. *Forms of Plant-crystals.*—The various forms of plant-crystals have been described by Gulliver, who distinguished four principal forms : raphides, sphæraphides (*drusen* of the Germans), short prismatic crystals, and long prismatic crystals.

The raphides have been the principal object of Gulliver's researches. They are frequent in Monocotyledons, and are found also in some families of Dicotyledons. Gulliver has described them in Vitaceæ, Balsaminaceæ, Galiaceæ, and Onagraceæ, and in numerous other orders of plants, but in the British Exogens so confined to the last three orders as to be characteristic of them ; *Hydrangea,* by its raphides, he finds sharply distinguished from the Saxifragaceæ, under which order it is usually placed ; and *Montinia* by its want of raphides as plainly differing from its assigned order, Onagraceæ.‡

The other crystals may be found free and abounding in the cavities of plant-cells, or one in every cell. The little prismatic, or tabular crystals, and the simple octahedrons, which are in many Gesneriaceæ, Bignoniaceæ, Scrophularineæ and Labiatæ, belong to the first case. To this also belongs, I think, the *crystalline powder* of *Sambucus* and of many Solanaceæ. To the second case belongs the greatest number of plant-crystals, especially those which are grouped in *druses* (very common in the pith and bark of ligneous plants) and the short prismatic crystals of the bast-cells.

* But see Beale's ' How to work with the Microscope,' 5th ed. p. 174, plate xlvii. for Gulliver's description and figures of sphæraphides of carbonate of lime.—ED.

† See "Bemerkungen zum Referate über Gulliver's Liste krystallhaltiger Pflanzen," von Prof. Dr. Georg Holzner, Zeitschr. f. Mikrosk., i. (1877), Heft 2, pp. 42–44.

‡ See this Journal, iii. (1880) p. 44 ; and Quart. Journ. Micr. Sci., 1866, and on Pollen, &c., in Pop. Sci. Review, 1868.

A very interesting form is that of crystals which are surrounded by an integument of cellulose, and fixed by this to the walls of the cell (see Pl. VI. Figs. 1, 2, and 3). They were seen first by Rosanoff (Bot. Ztg., 1865,) in *Ricinus* and *Kerria Japonica*, and afterwards in many Araceæ, in the fruit of *Rosa* (by Poulsen, who named them Rosanoff-crystals), in the pith of many Malvaceæ (*Sida*, *Hibiscus*, *Lavatera*, &c.) in the *Rigellaria Africana*, *Mercurialis annua*, and some Celastraceæ and Rhamneæ. These ligaments of cellulose are perforated, tubiform, and in the Malvaceæ they are found also in the cells which do not contain crystals, but in continuation of ligaments which surround the crystal of the contiguous cell (Fig. 3 *bis*).

Crystals are found also in the walls of cells, in the epidermic cells of many species of *Sempervivum* and *Mesembryanthemum*, and in the fibres of liber of many Coniferæ (Solms-Laubach and Pfitzer).

IV. *Plant-crystals as a Taxonomic Character.*—Crystals are not frequent in Cryptogameæ and Gymnospermeæ; but in the Angiospermæ they form the constant character of many families and groups of plants. Gulliver has proved the constant presence of crystals, and especially of raphides, in certain plants. He has found raphides in many orders, of which examples occur in Vitaceæ, Mesembryanthemeæ, some Nyctagineæ, in Balsaminaceæ, Onagraceæ, and Galiaceæ; and in the British flora he defines the Balsaminaceæ as Geraniales abounding in raphides, the Orchidaceæ as Gynandrous Endogens abounding in raphides, and Galiaceæ as Corollifloral Exogens abounding in raphides. Vesque * has found that the presence of raphides is a constant character of Dilleniaceæ. We may then define Dilleniaceæ as *Ranales* with raphides.

In the Lemnaceæ the genus *Lemna* contains raphides, the genus *Wolfia* is wanting in raphides. Vitaceæ contain every form of crystals in the stem, leaves, and fruit. Almost all ligneous plants contain sphæraphides in their pith and bark, and short prismatic crystals in the bast-fibres and sometimes in the wood (*Clusia*). Celastraceæ and Rhamneæ contain Rosanoff-crystals in the pith and the bark (Fig. 3). The bark and pith of many herbaceous plants (e. g. Labiatæ), contain free, abounding, little crystals. Many Monocotyledons contain only raphides (e. g. Orchidaceæ, *Narcissus*, many Liliaceæ, &c.); the *Iris* has long prismatic crystals, Araceæ raphides and sphæraphides. (In my abovementioned work there is a list of plants which contain crystals.)

V. As to the *physiological function* of crystals in plants we know very little. It seems that oxalate of calcium is a useless product of plants, because it is often eliminated from the plant by the fall of dead leaves and old bark; it is generally accumulated

* Vesque, " L'Anatomie des tissus appliquée à la classification des Plantes," Nouvelles Archives du Muséum d'Hist. Nat., iv. (1881).

in those parts of the plant, every function of which has ceased, and where it is formed it remains, and is not dissolved again. (In Dr. Beale's work above cited, are observations by Gulliver on the uses of plant-crystals.)

In the herbaceous plants, crystals abound in the axis of the inflorescence and stalks of flowers; and in *Ricinus* I have observed that there are an abundance of sphæraphides in the female flowers, while they are almost wanting in the male flowers (see Fig. 7). In small plants of *Ricinus*, crystals appear first in the glands of cotyledonary leaves by the side of the spiral vessels (see Fig. 8).

SUMMARY

ZOOLOGY AND BOTANY

(*principally Invertebrata and Cryptogamia*),

MICROSCOPY, &c.,

INCLUDING ORIGINAL COMMUNICATIONS FROM FELLOWS AND OTHERS.*

ZOOLOGY.

A. GENERAL, including Embryology and Histology of the Vertebrata.

Symbiosis of Dissimilar Organisms.†—G. Klebs, starting with the principle that the life of every organism is necessarily bound up with the life of others, directs attention to some of the general conclusions derivable from a study of symbiosis.

A great step in advance was made when P. J. van Beneden distinguished commensalists and mutualists from true parasites, even though these divisions and their definition may require some amendment. When one organism lives in or on another, this relation may be due to one of two sets of causes; we have cases in which only one of the organisms is more or less compelled to be associated for some part of its life with another; here we have the proper relation of host and guest, or one-sided adaptation. In other cases it is necessary, that the two symbiosists should live together, and here we have mutual adaptation, though one may be more dependent on its fellow than the other on it.

The author in what follows confines himself to the former set of cases, pointing out that the essential part of the relation is taken by the organism which seeks out the other, often larger, and often also more highly organized, for the purpose of fulfilling its own mode of life. Any one who has examined life in a pool or in the sea knows that almost every large organism, be it plant or animal, is covered with a number of smaller ones; this is the simplest case of symbiosis: smaller organisms make use of the surface of the larger one; thus algæ will be found covered with diatoms; every tree on land is beset with algæ, lichens, and mosses, and often there is a definite relation between them and the kind of tree on which they live. Various plants,

---

* The Society are not to be considered responsible for the views of the authors of the papers referred to, nor for the manner in which those views may be expressed, the main object of this part of the Journal being to present a summary of the papers *as actually published*, so as to provide the Fellows with a guide to the additions made from time to time to the Library. Objections and corrections should therefore, for the most part, be addressed to the authors. (The Society are not intended to be denoted by the editorial " we.")

† Biol. Centralbl., ii. (1882) pp. 289-99.

especially algæ, attach themselves to snails or mussels, and even to such actively moving forms as *Cyclops* or *Daphnia*. Numerous examples of animals are then cited; such as *Vorticella, Epistylis*, Sponges, Hydroid Polyps, Bryozoa. In some cases (crabs and sponges) a rapacious host hides himself under the cover of his guest.

Cases of higher symbiosis, in which the guest is not external, are next entered upon, and it is pointed out that, in addition to all these cases in which the host is always passive, there are others in which there is some kind of reaction between guest and host; thus the crustacean *Cryptochirus coralliodytes* affects the streams of water which pass to the polyps of its coralline host; and corals are very frequently indeed affected in form by the crustacea or mollusca that give in them. In conclusion the author thinks that we gain but little information as to the cause of these symbiotic phenomena, if we are content to say with Van Beneden that there is a "sympathy" between the host and guest.

Electric Organs of Gymnotus.—G. Fritsch has two appendages to Sachs and du Bois Reymond's great work [*] on this fish, in which he gives an account of his histological and morphological investigations into the nervous and electric apparatus; he finds support for the doctrine that the electric organs of *Gymnotus* have been developed from transversely striated muscle, a portion, the lowest lateral muscles, having been separated from the rest to form the so-called intermediate muscular layer, while a superior mass of muscle was converted into the great electric organ. The two are surrounded by a common fascia, which separates them from the so-called small organ which owes its origin to a metamorphosis of the muscles of the fin-rays. No explanation can yet be given of the remarkable variations (within 50 and 100) of the number of electrical columns. Every electric plate of *Gymnotus* arises from a certain number of primitive muscular bands which become connected together in their middle; the separate pieces of the compound plates do not, however, seem to correspond to a primitive bundle, but to a primitive cylinder (Cohnheim) of the embryonic muscle. The mode of termination of the nerves may be most nearly compared with what is seen in the pseudo-electric organ of *Raja*; the spongy tissue around the nerve-endings and "thorny papillæ" is a supporting substance, directly continuous with the sheath of Schwann.

In the description of the central nervous system attention is directed to the rounded form, well-developed cell-protoplasm, and broad attachment of the process of the axis-cylinder in the characters of the fully developed electric cell.

B. INVERTEBRATA.

Intracellular Digestion.[†]—E. Metschnikoff directs attention, in this connection, to the hydroid parasite found by Owsjannikoff in the egg of the sterlet; in the endodermal cells of that parasite were to be

[*] 'Unters. am Zitteraal' (Sachs und du Bois Reymond) 446 pp. (8 pls.) 8vo, Leipzig, 1881.
[†] Zool. Anzeig., v. (1882) pp. 310–6.

seen small highly refractive granules, which "undoubtedly owed their origin to nutrient matters taken into the interior of the cell." The author is of opinion that in the Turbellaria and Cœlenterata (inclusive of Sponges) intracellular digestion is the general rule; a very suitable form for its demonstration is stated to be young Ctenophores, for in them the whole process can be followed out to the end (i. e. till the time when crystalline concretions appear within the vacuoles) in one and the same individual. The opinion of Krukenberg that colouring matters are indigestible, is not supported by the author's observations, carmine, for example, being distinctly absorbed; and Eisig has lately shown that carmine is digested in the intestinal canal of the Capitellidæ and excreted by their segmental organs. Some other remarks of Krukenberg are closely criticized, and are regarded by Metschnikoff as not really affecting the reality of intracellular digestion in the lower forms.

Mollusca.

Nervous System of Mollusca.*—W. Vignal finds that the nerves are surrounded by a sheath of connective tissue of some thickness, which is formed of imbricated lamellæ, containing a number of nuclei; in the terrestrial pulmonate Gasteropoda the true sheath is invested in a second, formed of a layer of vesicular cells, which is not however, proper to the nerves, as it is found also on the vessels. From the true sheath there are given off a number of partitions, made up of several lamellæ, which pass towards the centre of the nerve; as they do so the lamellæ divide afresh and unite one with another to form spaces of various sizes, in which we find the axial portion of the nerve-fibrils, and the protoplasm which surrounds them. While there are a number of nuclei in the partitions there are none in the protoplasm: the sheath is not to be compared with the sheath of Schwann in the Vertebrata, but if it is to be compared with anything found in that phylum, it must be with the intrafascicular connective tissue. This peculiar structure of the envelope of the nerve-fibres is, it is remarked, found very generally among the Invertebrata, something analogous being found in both Hirudinea and Lumbricidæ. Its presence affords an explanation of the difficulty of dissecting out any length of nerve-fibrils. These fibrils themselves spread over the surface of the ganglia and penetrate some way into their interior; in this region the protoplasm contains a number of fatty and pigmented granulations, which would appear to form a reserve used up by the animal in the winter, as they are much more numerous (in *Helix*) during the summer than they are at the end of the period of hibernation.

The author finds that for the demonstration of the partitions chloride of gold is the best reagent, for they are coloured by it while the nerve-fibres are almost unstained; if the section is then decolorized by cyanide of potassium, and afterwards treated with picro-carminate of ammonia, the nuclei are very easily seen. The fibrils are best demonstrated by a mixture (in equal parts) of osmic and chromic

---

* Comptes Rendus, xcv. (1882) pp. 249–51.

acids; after it has been used for the specimens hardened in alcohol, the sections may be coloured by hæmatoxylin, and afterwards decolorized by very dilute formic acid.

North-American Cephalopods.[*]—Professor A. E. Verrill has published the second portion of his paper,[†] in which he deals chiefly with smaller forms, though the commencement is occupied by an account of a young example of the gigantic *Architeuthis harveyi.*

Observations on the habits of squids tell us that the fish captured are devoured with great rapidity, and it would seem that the jaws are the principal organ, while the odontophore plays only a subordinate part. The differences in anatomical structure between *Loligo* and *Ommastrephes* are carefully pointed out; in the latter there is not one large, but two small oviducts, and the nidamental glands are smaller and simpler; though, it is to be remembered, they were not examined in the breeding season.

A new genus, *Chiloteuthis,* allied to *Enoploteuthis,* is formed for a creature with a very complicated armature; the sessile arms have sharp incurved claws, arranged in four rows on the ventral arms, and in two rows on the others; other characters are detailed and an account is given of *C. rapax* n. sp. The family Desmoteuthidæ is formed for genera which have been confounded hitherto with the Crambidæ and Loligopsidæ; *Desmoteuthis* n. g. has for its type *Leachia hyperborea.*

The sexual differences in *Loligo pealei* are examined, and it is stated that the hectocotylized condition of the arm in the male is, contrary to the opinion of Steenstrup, developed in proportion to the development of the internal organs, and is not noticeable in the youngest males. Notes on the development and rate of growth follow.

A new species of *Rossia* (*R. megaptera*), remarkable for the great size of the fins and eyes, and for the length of its tentacular arms, was taken off the southern coast of Newfoundland. It appears to be a species adapted for greater depths than its congeners.

Another new family is that of the *Alloposidæ,* allied in some respects to *Philonexis* and *Tremoctopus.* The arms are extensively webbed; the mantle-edge, as in *Desmoteuthis,* is united directly to the head.

In an appendix the author describes several other new forms, and enters into some critical remarks on the work of other naturalists.

Marginella and the Pseudomarginellida.[‡]—J. Carrière commences with a notice of the four zones found at the island of Goree, each of which has its own fauna, different to that of the other zones. In the deepest we find, among other molluscs, *Marginella glabella.* The statement of Adanson that *Marginella* is to be found in the upper zone is not exact, for the shells there found, and so called, belong to quite a different kind of mollusc. Till lately the animals which

---

[*] Trans. Connect. Acad. Sci., v. (1882) pp. 259–446 (28 pls.).
[†] The first portion in tom. cit. pp. 177–257.
[‡] Zeitschr. f. wiss. Zool., xxxvii. (1882) pp. 99–120 (1 pl.).

inhabit these shells have not been detected, and the resemblance between the shells of the upper and those of the lowermost zone are so close that no conchologist is to be blamed for associating them with one another. On closer examination, however, of the internal structure, very important differences are to be detected, and the whole account is so instructive that we give a *résumé* of the author's table of differences.

The three forms may be distinguished as *M. glabella, Pseudomarginella leptopus,* and *P. platypus.* In all cases the shell is that of *M. glabella,* but while the foot of the form properly so called is broad, flat, and tapers posteriorly, being red in colour, that of *P. leptopus* is narrow and high, of the same breadth throughout, and colourless, save for black spots at the sides, and that of *P. platypus* is broad, flat, the same breadth throughout, and colourless. So, again, the operculum is either absent, or is like that of *Fusus* (unguiculate), or is lamellar, as in *Purpura.* The tentacles of *Marginella* are long, the radula has only the middle plates, and these are broad and provided with a number of small teeth, while the pedal gland is large in proportion to the foot. In both Pseudomarginellids the foot-gland is very small; in *P. leptopus* the tentacles are short and broad, while in *P. platypus* they are short and round. The lateral plates of the radula are, in the former, broader than the median plate, but in the latter they are unciform and much smaller. Indeed, *P. leptopus* appears to belong to the Buccinacea, while *P. platypus* is probably one of the Purpuracea.

It is pointed out that, thanks to the investigations of Semper, we know that the very opposite of the conditions here described may in some cases be found to obtain; that is to say, there are forms (*Chlorœa* and *Dorcasia*) in which, though the animals are closely allied, the shells themselves are very different. The studies of later years show that shells with a large wide orifice are very variable; and now we find that *Marginella* is a form with a narrow orifice. The author insists on the important bearing which observations of this kind have on the determinations of palæontologists and the theories of stratigraphical geologists.

Vascular System of Naiades and Mytilidæ.*—Dr. H. Griesbach gives a preliminary notice of his studies on this subject, which has always attracted much attention, in association with the taking of water into the body of these molluscs. The animals were placed in water coloured by green iodide; and the coloration was sooner or later noticeable in the foot, whence it extended into the most various regions of the body. Owing to the chemical changes which take place in *Anodon,* owing to the presence in its tissues of a large quantity of calcareous salts, the tissues will be found to be coloured violet. The author has been able to force injections through the slit-like orifice in the foot (one of which lies quite anteriorly, and the other two at about the middle). The colouring matter may be observed to pass not only into the larger trunks, but also, with care and patience, may be detected in the vessels of the muscles of the foot.

* Biol. Centralbl., ii. (1882) pp. 305-9.

The author promises to give further details, and to demonstrate how the openings are connected with the blood-passages. He regards the water that is taken as having a respiratory as well as an erectile function.

Sexuality of the Oyster.*—M. Bouchon-Brandely points out that, while the common oyster (*Ostræa edulis*) is hermaphrodite, the Portuguese form (*O. angulata*) is unisexual. In the latter the ova are expelled from the shell and fertilized in the water. The characters of their development are such as to yield no support to the doctrine of hybridization taught by some French ostreiculturists, and artificial fertilization of the two species has never yet been found to be successful. Artificial fecundation of *O. angulata* was, however, effected, and it was observed that the shell is formed on the sixth or seventh day after impregnation. The genital gland of this species does not have its elements matured until the time when it becomes transparent. Having been successful in small attempts at artificial fertilization, the author has successfully attempted some experiments on a much larger scale.

Arthropoda.

α. Insecta.

Respiratory Movements of Insects.†—F. Plateau finds, as the chief results of his experiments, that—

1. There is no close connection between the character of the respiratory movements of an insect and its systematic position. The respiratory movements are only analogous when there is very nearly the same structure of the abdominal rings, and of the muscles which move them. For example, the respiratory movements of the Phryganida do not resemble those in allied Neuroptera, but are much more similar to those of the aculeate Hymenoptera.

2. In *all insects* the diameter of the abdomen diminishes during expiration, owing to the approximation of the tergal and sternal pieces. The former, as in the Coleoptera, may alone be mobile, or the latter, as in Acrididæ, Libellulidæ, Lepidoptera, and Muscidæ; or the two may move equally, as in Tipulidæ, *Sialis*, and a few others.

3. The modifications in the vertical diameter *may* be accompanied by changes in the transverse diameter, as in the Libellulidæ, Chrysopidæ, some Coleoptera, &c.

4. Contrary to what was formerly believed, it has been found that, during normal respiration, changes in the length of the abdomen are rare; they are to be seen in the aculeate Hymenoptera, and in such isolated cases as the Phryganidæ among the Neuroptera, and the Coccinellidæ among the Coleoptera.

5. In most cases the thoracic segments take no share in the respiratory movements when the animal is at rest, but they have been observed to do so in some genera of Coleoptera.

6. Contrary to the opinion of most observers, M. Plateau thinks that the respiratory wave is an exceptional phenomenon. It has not

---

* Comptes Rendus, xcv. (1882) pp. 256–9.
† Bull. Acad. R. Sci. Belg., iii. (1882) pp. 727–37.

been observed in any of the Coleoptera, the Acridida, *Libellula*, aculeate Hymenoptera, Muscidæ, and all Lepidoptera.

7. When there is a pause it is almost always during the inspiratory phases.

8. In large forms, suitable for such investigation, it has been observed that inspiration is ordinarily slower than expiration, and that the latter is often very rapid.

9. In most insects expiration only is an active movement, while inspiration is passive, and due to the elasticity of the integument, and of the walls of the tracheæ.

10. Inspiratory muscles are rare, but have been found in the Phryganidæ, as well as in the Hymenoptera and Acrididæ.

11. The so-called upper diaphragm, or *alæ cordis*, as well as the lower, have not the function attributed to them by Wolff.

12. A large number of insects, perhaps all, impress on their abdomen general movements, which vary in intensity, but do not coincide with the respiratory movements proper.

13. These last are purely reflex, and persist after decapitation, and even (when the nervous system is not concentrated) when the abdomen itself is isolated. In it the movements may be hastened or retarded by just the same external causes as produce the same phenomena in the uninjured animal.

14. The metathoracic ganglia are not special respiratory centres.

15. The abolition of the respiratory movements, on the destruction of the metathoracic ganglia, which is to be seen in *Dytiscus* and some other Coleoptera, is due to the concentration of their nervous centres, some abdominal being fused with the thoracic ganglia.

16. In insects with a concentrated nervous system, the excitation or partial destruction of a complex nervous mass affects all the centres which enter into the composition of it.

These important and interesting results are due partly to the use of the " graphic method," the movements being inscribed on a rotating blackened cylinder. In addition to this, a " method by projection " was used. An insect fixed by a slight support, and in such a way as not to affect its respiratory movements, is introduced into a large, well-illuminated magic lantern. The objects of the investigation— the respiratory movements—are then thrown upon a screen, whence they can be drawn on a sheet of paper. Displacements of a fraction of a millimetre can thus be followed. This latter method is a modification of that of Professor Valerius. Further details will be given in the complete memoir, of which this is only a preliminary notice.

Location of Taste in Insects.[*]—J. Künckel and J. Gazagnaire have studied minutely the anatomy of the *epipharynx* (labrum of authors) and *hypopharynx* in the Diptera. They form two troughs, whose concavities are opposite each other, the hypopharynx being embraced by the margins of the epipharynx. In *Volucella* the walls

---

[*] Comptes Rendus, xciii. (1881) pp. 347-50.

of the latter become less rigid towards their margins, which are membranous. Just above them the internal face of the organ is beset with small modified hairs, arranged with regularity; the anterior end is armed with six pairs of straplike organs, jointed at the base and minutely spined, some of which serve to sweep pollen from the corollæ of flowers; the ventral pair carry 10 or 12 modified hairs in front of the joint.

Passing by the arrangement of the muscles in the epipharynx, we come to its nerves. They are derived from the supra-œsophageal ganglia; about half-way along the epipharynx they approach the middle line and break up into a number of fibres which are connected with the modified hairs which occur on the extremity, other fibres having been already distributed to the hairs which fringe the margins of the epipharynx. At the base of these hairs (which are button-like and placed on pointed chitinous processes) the neurilemma forms small swellings, and the axis-cylinder ends in a fusiform cell provided with nucleus and nucleolus, whose distal extremity becomes attenuated and terminates at the base of the protuberance which surmounts the button.

The hypopharynx has its membranous ventral wall reflected over the dorsal wall of the labium and covered with small hairs; its anterior extremity carries five spines. The space between its two walls opens towards the labium in front, and to the pharynx below; at this point the salivary duct also opens, and the salivary secretion is thus liberated opposite to the very spot on the epipharynx above, on which the terminal nerve-endings are situated. By this arrangement the saliva, charged with digested matters, meets these nerve-endings and evokes in them a gustatory sensation from the matters which it holds in solution. Taking this in connection with facts previously determined, it seems reasonable to conclude that gustation in the Diptera commences with the paraglossæ, at the point at which the false tracheæ open, is continued along the false tracheæ and becomes intensified at the extremity of the epipharynx, where quite a bouquet of nerve-endings occurs; it is prolonged along the margins of the epipharynx and operates at the entrance or throughout the cavity of the pharynx.

Parthenogenesis in the Bee.*—G. Ulivi considers that parthenogenesis in the bee is a myth, the result of his observations being as follows :—

1. Queens are usually fertilized inside the hive. On their return from the so-called "marriage-flight" they had empty spermathecas, while the act of fertilization was repeatedly witnessed in the hive.

2. They are fertilized several times.

3. Drones are not mutilated in the act of copulation. No lacerated drones were found after several careful examinations of all the drones in hives in which impregnation had taken place, and the whitish appendage attached to the queen's abdomen on her return from the "marriage flight" was found to consist of excreta.

* Amer. Natural., xvi. (1882) pp. 680-1, from the report of G. F. Krœh in the 'Scientific American,' 25th March, 1882.

4. Every egg that hatches into a male or female has been previously fecundated. Queens that had been allowed to fly were afterwards confined in hives containing no drones or drone brood, and either laid no eggs, or laid eggs that did not hatch.

5. Every queen whose spermatheca is distended and filled with liquid has been fertilized.

6. The eggs of a queen that has never met a drone will not hatch.

7. There is no such thing as a fertile worker. Fertile eggs will keep through the winter and hatch in the spring, and this hatching of fertilized eggs in queenless colonies has led to the belief in fertile workers.

"The investigations," writes W. N. L.* "appear to have been carefully and thoroughly conducted, and every result is based upon repeated observations. Should they be confirmed, not only will the theory and practice of bee-keeping be revolutionized, but another example will be added to the many that go to prove how slow mankind should be to accept as true, conclusions opposed to the ordinary laws of life. The continued reproduction of the aphides, sometimes called parthenogenesis or virgin maternity, is really of a very different nature. It is a process of budding differing from the budding of a zoophyte chiefly in the fact that it takes place upon an internal instead of upon an external surface."

Eye of Chloe diptera.†—In this Ephemerid, according to G. V. Ciaccio, the male, in addition to the compound eyes and ocelli of the female, has two large accessory compound eyes. He has discovered that these eyes "are distinguished in a marked manner from the ordinary ones, not so much by differences in their colour and form and the greater size of the crystalline cones, as by the fact that the optic rods do not consist each of a single piece but of two differently shaped and quite distinct portions, the one anterior, the other posterior." The first has the form of a six-sided prism and is about the same size as the rods of the ordinary eyes; it consists of a whitish filament containing a coloured granular substance. The second is a single filament, endowed with a peculiar refractive power, and is a prolongation of the first. In order to reach their respective cones, all the filaments traverse together a substance composed of large granules of a dirty white colour, verging on yellow.

In the stemmata, moreover, there is a large biconvex crystalline lens, placed just behind the cornea, which is curved, thin, and "tessellated behind with small cubical cells." It also seems to Ciaccio worthy of careful consideration, as not hitherto noticed in other insects, that the lens is not chitinous, but consists of a peculiar, rather soft substance, fairly transparent, containing a reticulation of very delicate fibres, with round or oblong nuclei placed at the nodes of the network. There is no capsule to the lens; its place is taken by a substance of the same character as that of the lens, but denser towards

---

the periphery.   The lens is kept in its place by a very delicate fibrillated tissue, perhaps representing the vitreous humour, intercalated between the lens and the retina.   The latter, like the simple eyes of the Diptera, is composed of rods and large fusiform cells, each of which is continuous with a fibre of the optic nerve.

Marine Caddis-fly.*—Mr. R. M'Lachlan describes and figures the larva of a caddis-fly (*Philanisus plebejus* Walker) which inhabits rock pools between high and low water marks in New Zealand, and forms its case of coralline sea-weed.   No truly marine form has hitherto been recorded, though at least one species lives in the brackish water of the shores of the Baltic, and several are found in salt marshes or pools occasionally invaded by the sea.

γ. Arachnida.

Respiratory Organs of Arachnids.†—J. Macleod, in a preliminary account of his observations on these organs, commences by stating that his earlier researches had led him to regard the lungs of Arachnids as a special form of trachea, or, in other words, as modified tracheæ, and in support of this it is pointed out that, while the tetrapneumonous Araneids have two, and the dipneumonous forms one pair of lungs, the latter have a pair of tracheal stigmata, comparable to the same organs in insects.

The lungs may be regarded as consisting of a cavity or chamber, the hinder portion of which opens to the exterior by means of a trans-

Fig. 109.
verse slit, the lips of which are provided with a thickened chitinous pad ; the chitinous lining of the cavity is continuous, at the stigma, with the cuticle of the external integument. Into the cavity there extend the lung lamellæ ; each of these is composed of two chitinous layers, the spaces between which are occupied as blood-passages ; for all the passages there is a common vestibule (Fig. 109), and the slits of all are similar to one another, with one exception ; the last, instead of being cylindrical, is more or less triangular, its chitinous cuticle is thick and carries a large number of spines well developed, and so arranged as to form a kind of second tunic.

With regard to the tracheæ in the Araneida, we see that they may be simple or branched, and their stigmata confluent or separated.   In an *Argyroneta*, in which they are well developed, there are two large cylindrical primary trunks, which open to the exterior by two

---

* Journ. Linn. Soc. (Zool.) xvi. (1882) pp. 417–22 (5 figs.).

† Bull. Acad. R. Sci. Belg., iii. (1882) pp. 779–92.

slits confluent along the middle line, and which give off a number of ramifications; the wall of each primary trunk is composed of an external chitinogenous wall, and an internal chitinous layer, covered by a large number of spines which unite with one another as in the last tube of the lung. The author believes that the tracheæ of *Argyroneta* are nothing else than the last slit of the second lung of *Mygale*, enormously developed, while the rest of the organ is obliterated.

A comparison between the lungs of Arachnids and the gills of *Limulus* is then entered upon, in which especial attention is directed to the work of Prof. Ray Lankester, which we have already noticed;

Fig. 110.
Fig. 111.
M. Macleod agrees in regarding the organs as homologues, but he thinks that their relations may be explained more simply than they

Fig. 112.

a

b
have been by the former. Let us begin by supposing that there is a considerable elongation of the abdomen of the *Limulus*, without any other change; the result of this modification would be that the respiratory limbs would no longer imbricate (Fig. 110). If, now, the sternal region should enlarge and fuse for its whole length

c

into the ventral, while the infero-superior axis were elongated, we should arrive at the abdomen of a scorpion, where each lung was replaced by a gill (Fig. 111). Each gill would be composed of a quadrangular plate fixed by its intimal edge A B, and its anterior edge B C (Fig. 112*a*), and free on the other two; this plate would serve for the

insertion of a certain number of delicate quadrangular lamellæ, only fixed along the edge $\beta\,\gamma$. If the animal passes to a terrestrial mode of life the flaccid lamellæ, which were previously supported by the water, will apply themselves to one another, and will only be very imperfectly in contact with the air. They will become attached by their faces. [The three diagrammatic figures represent the modifications which have probably been undergone by the gill of a *Limulus* in becoming converted into the lung of a scorpion. *a Limulus, b* an intermediate stage, *c* a scorpion, *st* sternal plate, A B C D respiratory limb, attached by A B to the sternal plate, $\alpha\,\beta\,\gamma\,\delta$ respiratory lamella. The dotted lines indicate where fusion has taken place, the black ones the presence of a free chitinous edge $\alpha\,\beta$ and $\gamma\,\delta$ to the wall of the depression in which they are placed. The chitinous plate (modified limb) which covers them will fuse by its external edge C D to the edges of this depression.]

In conclusion, doubt is thrown on the protracheate nature of *Peripatus*, and the suggestion is made that the respiratory organs of the Arachnida are not homologous with those of the Insecta.

Habits of Scorpions.*—Professor E. Ray Lankester records some interesting observations which he has recently undertaken on *Androctonus funestus* and *Euscorpius italicus.*

Of *Androctonus* he relates their mode of burrowing in sand, making horizontal tunnels which are often as much as 8 inches long. They commence by pushing the large chelæ into the sand and scraping very rapidly backwards with the three anterior pairs of walking-legs, this use of the legs comparing with the parallel but not identical use of the legs in *Limulus*. They were evidently timid, hiding in the daytime. Their carriage is remarkable, as in walking they raise their body well from the ground, the tail reflected over the back, and the sting carried just over the cephalic shield ready to give

* Journ. Linn. Soc. (Zool.) xvi. (1882) pp. 455–62 (3 figs.).

a forward stroke, the large chelæ widely outstretched and held horizontally, the creature feeling its way with them.   They only feed at dusk or at night.   The prey is seized by the left chela, and at the same moment the sting is swiftly brought over their head and the victim pierced with it.   The short cheliceræ are then inserted into the soft substance of the prey and the nutriment brought to the mouth by alternate movements of the right and left cheliceræ.   The combs or pectiniform appendages ordinarily do not appear to possess any special sensitiveness, but they may possibly become more so during the breeding season.   The well-attested statement of the suicide of the scorpion when surrounded by a ring of red-hot embers, may perhaps be explained by the fact of some individuals accidentally lacerating themselves with their sting when half suffocated; Professor Lankester having seen a scorpion under the influence of chloroform vapour make repeated blows with its sting in the forward direction straight above its head until the top of the sting caught under the free projecting margin of the posterior region of the cephalic shield.

The body of *Euscorpius* is kept close to the ground, the legs extended on either side, the tail being dragged behind with the slightest upward curvature only, or one to the right or left.   In fighting one another the large chelæ were used but never the sting. In stinging their prey they do so with great deliberation, the slowness of the process being perhaps due to the fact that the poison-glands have to be compressed by their proper muscles, and the poison squeezed out of the lumen of the gland after the sting has pierced the prey.

Nest-forms of the Furrow Spider.* — Dr. H. C. M'Cook has observed that some of the orb-weaving spiders have a marked tendency to vary the forms of their nests.   The spinning-work of spiders may be classified as (1) the *snare*, spun for the capture of prey; (2) the *enswathment*, by which insects are disarmed and prepared for food; (3) the *gossamer*, used for purposes of aqueous or aerial locomotion ; (4) the *cocoon*, spun for the propagation and protection of the species; and (5) the *nest*, which is a domicile more or less elaborate and permanent, within or under which the araneid dwells for protection against enemies and weather-changes.   As a rule the great groups of orb-weavers differ from each other and agree within themselves in the characteristic form of nest.   The form prevailing in each family is substantially the same; each species appears to adhere quite steadily to one characteristic form; but there are some marked variations in the habit of certain species, the most decided of which have been observed in the case of *Epeira strix*, the furrow spider.   He gives some examples of this.

The ordinary nest when domiciled in the open field or wood is a rolled leaf.   A second form varies from the rolled-leaf nest in having the edges of two adjacent leaves bent towards each other and lashed together on the exterior at the juncture by silken cords and on the interior by adhesive tissue web.   An oval opening is left at the united

* Proc. Acad. Nat. Sci. Philad., 1882, p. 97.

points of the leaves, through which the connecting-line passes to the snare. The spider domiciles within the leafy cavern thus formed.

Again, the spider avails herself of small holes in wood or stone, openings in fences, the interspace between curled bark on the trunk of old trees, or some like cavity, which she appropriates as a nesting-place.

Another variation was due to an accident in the environment of the web. A colony of carpenter ants dropped their chippings on the web until a ball as big as a walnut had accumulated, which was then utilized by the spider as a nest, the interior being bored and silk-lined.

Other special variations are noted, including that of the nest attached to exposed parts of human habitations, such as the cornices of porches, outhouses, &c., and " it is thus seen that while there is a general regard to protection of the spider's person, there is a modification over a quite wide degree of variation in the form of the protective nest; further, that this modification appears to be regulated, more or less, by the accidental environment of the domicile, and in such wise as to show no small degree of intelligence in adapting the ordinary spinning habit to various circumstances, and to economizing labour and material."

Parthenogenesis in the House Spider.*—Mr. F. Maule Campbell details some interesting observations on a probable case of parthenogenesis in *Tegenaria guyoni*, one of the females of which, after a confinement of eleven months, twice moulted and afterwards laid eggs which were duly hatched. This shows either that she was impregnated previous to the casting of the two exuviæ, in an early and therefore immature stage, or that parthenogenesis occurs in the Araneidea. Hitherto no instance of virgin production has been recorded in the true spiders, though Mégnin, Kramer, Haller and Michael have shown that the females of some Acarina couple with the males prior to their final moult, and that practically there are two stages of sexual maturity. Beck and others have also related cases of undoubted parthenogenesis in the *Acari*.

Segmentation in the Mites.†—P. Kramer describes the segmentation of a minute mite, *Alycus roseus*. The dorsal aspect shows a very distinct segmental line between thorax and abdomen. The abdomen shows nine distinct segments, which follow one another exactly as in *Podura*. The segmental grooves between the first three are broad, and present somewhat the appearance of double lines, of which the anterior cut off the preceding segment, and the posterior commence the succeeding one. The lateral margin of the abdomen shows distinctly the convexities and constrictions which correspond to the middles and boundaries of the segments. The setation throughout follows the segmental conditions. The hindermost segment bears the perfectly terminal anal aperture, half of which

* Journ. Linn. Soc. Lond. (Zool.) xvi. (1882) pp. 536-9.
† Arch. f. Naturg., xlviii. (1882) pp. 178-82 (figs.). Ann. and Mag. Nat. Hist., x. (1882) pp. 183-4.

is seen in the dorsal view, while the other half is seen in the ventral.

On the thorax there is a distinct pair of eyes, furnished with very convex lenses, just as in *Rhyncholophus*. It further bears several long setæ, of which the pair situated between the eyes is distinctly fringed. This special pair of setæ on the thorax when seen under a low power, especially as it is placed near the black eye-spots, leads one to suppose that we have here a respiratory organ, similar to the stigma of the Oribatidæ; but a higher power shows distinctly that they are nothing but an ordinary capillary structure. On the thorax there are also three longitudinal lines, branched in a tree-like fashion behind, and two transverse lines; and these divide its whole dorsal surface into several areas, three of which occupy the entire central space.

On the lower surface the thoracic segmental lines are seen distinctly running between the coxal plates of the second and third pairs of legs. The segmental lines of the back also pass on to the lower surface bending forward in the middle of the abdomen. The segmental lines of the more anteriorly situated abdominal segments could not be distinctly traced on the lower surface.

δ. Crustacea.

Perception of Colour by Crustacea.*—C. De Merejkowsky following Sir John Lubbock's investigations into the perception of colour by the lower animals, has experimented on Crustacea, especially larvæ of Cirripedes and a Copepod. In darkness, the animals disperse to all sides of the vessel in which they are kept; if daylight is admitted through a slit, they congregate near the slit, and behave similarly towards monochromatic light, of whatever colour. Using two slits at an angle of 40° with each other and admitting white light by one and a monochromatic light by another, he finds that most, if not all, prefer the white light, but pale colours (yellow, green, pale red) also attract a few individuals. When two monochromatic lights are used, the brighter is preferred; with two rays of equal brightness the animals are equally divided between the two. Any superiority in the amount of light admitted attracts the bulk of the colony, whether the light is monochromatic or not. Thus it is seen that these animals appreciate only the quantity of the light, or the intensity of the vibrations which produce it, and are only sensitive to colour as implying a certain amount of light.

Mediterranean Crustacea.†—L. Joliet describes a parasitic Crustacean which he found under the form of small, ovoid, reddish bodies in the general cavity of the Alcyonarian *Paralcyonium elegans*. Not at all unlike a tardigrade at first sight, their two pairs of antennæ and the form of the hinder end of their bodies showed that they could be nothing else than crustaceans. The author soon found that the creature under examination belonged to the genus *Lamippe*, of which

* Comptes Rendus, xciii. (1881) pp. 160–1.
† Arch. Zool. Expér. et Gén., x. (1882) pp. 101–20 (1 pl.).

only two species have yet been described; one was (1858) found by Bruzelius in *Pennatula rubra*, the other by Claparède in *Lobularia digitata*. The species now studied was found to change its form incessantly during life, so that at one time it was cylindrical, and at another rounded, and it might just as well as Claparède's species have received the specific name of *proteus;* a kind of soft parenchyma, charged with globules, which are probably fatty in nature and are coloured red, fills the body and renders it almost opaque. The delicate chitinous membrane which envelopes the body presents no trace of permanent annulation, but only temporary constrictions, which correspond to any given state of contraction of the body. Of the details of structure we can only say that, so far as the nervous system is concerned, all that the author could discover was a small refractive thickening near the eye, to which he is in doubt whether or not he should apply the term of ganglion; the eye, itself, is unpaired though double, and is to be found on the dorsal side a little behind the rostrum. The nauplius-form was detected and some of its characters were made out.

This third species has been named *Lamippe duthiersii*. As to its exact systematic position there would seem to be some not inconsiderable doubt, but it certainly is Crustacean, and, owing to the polymorphism exhibited by the parasitic Copepoda, we may for the present regard the Lamippidæ as forming a special division of that group.

The next subject discussed by Joliet is that of the functions of the dorsal feet in the Notoproctous Crustacea. It is a well-known fact that the *Dromiæ*, especially when young, hide themselves under a kind of carapace, formed by a sponge or an alcyonium which they hold on their back by the aid of their hinder feet, and he has observed and here enters into full details with regard to the habits of these Crustaceans; he finds also that the Dorippidæ do the same thing, and, though there is some difference in the anatomical structure of these two sets of forms, there is no doubt that they have the same habit of hiding themselves under various objects either to protect themselves against their enemies, or to hide themselves from their prey.

Pontonia diazona n. sp., presents an instance of mimicry. The Ascidian genus *Diazona* is very common at Mentone; having placed a small quantity of the masses formed by these creatures in clean water, the author was, shortly afterwards, surprised to see a small Crustacean swimming freely about. From a distance the animal could only be detected by the movements that it made in the water, so completely transparent was it. Left to itself, it soon re-established itself on the *Diazona*, where the transparent parts became so completely confounded with the hyaline structures of the Ascidian, and the yellow parts agreed so completely with the yellow markings of the colony, that it was only by shaking or by previous knowledge that its existence could be detected. It was not possible to discover whether it was a true parasite, or only a commensal, but its coloration and its habits are sufficiently striking examples of mimetic action to justify

attention being drawn to it. A technical account is given of the specific characters, but the author was unfortunately unable to draw the creature while it was fresh; the characteristic coloration dis-disappears after preservation in alcohol.

North American Crustacea.*—S. I. Smith has some notes on the zoea-forms of *Pinnixa*, distinguishing a long-spined and a short-spined series, and he describes the characters of the adult *P. chætopterana*, and *P. sayana*. He directs attention to the occasional occurrence of tropical and sub-tropical species of Decapod Crustacea on the coast of New England, and summarizes the information that has been collected regarding these forms.

In giving an account of some genera of Amphipods, he says that in several forms the excrement enters largely into the formation of the tube. A species that was placed in a small trough with algæ pulled towards each other a few slender branches of the alga; these were fastened by threads of "cement spun from branch to branch by the first and second pairs of peræopods." When the tube had nearly attained its complete form it was still usually nothing but a transparent network of cement threads with here and there a small piece of alga. Soon after this the animal began to work into it pellets of excrement and bits of alga; the former seized by the more anterior appendages were broken into minute fragments and worked through the web. This went on till the whole animal was protected from view; the process of construction would seem to take about half an hour. All the tubes are black externally, thin, and cylindrical; within they are lined by the cement; they do not seem ever to be attached, but to be carried about by the animal.

New Copepoda.†—S. A. Forbes records new genera and new species of Copepoda from Lake Michigan and pools in Illinois. *Osphranticum* nov. gen. is similar to *Diaptomus* in general appearance, but differs especially in the structure of the fifth pair of legs of male and female. *O. labronectum* is the single species. *Epischura* nov. gen., in the general character of the legs both natatory and clasping, stands near *Heterocope* of Sars, but is remarkably distinguished from all other Copepoda by the development of the abdomen of the male as a prehensile organ, the second and third of the five segments are produced on the right side as large and strong processes which act against each other like forceps, while a toothed plate on the fourth segment and a spatulate one on the fifth assist to form a peculiar and powerful grasping apparatus. "A steel trap attachment to the tail of an alligator would," the author says, " very well illustrate the vigorous embrace of the animal " (*E. lacustris* nov. sp.). In addition, three new species of *Diaptomus* (*D. sicilis, D. leptopus,* and *D. stagnalis*), and two new species of *Cyclops* (*C. thomasi* and *C. insectus*) are described.

In ten "bladders" of *Utricularia vulgaris*, taken at random, 93 animals, either entire or in recognizable fragments, were found, repre-

* Trans. Conn. Acad., iv. (1882) pp. 243–84 (1 pl.).
† Amer. Natural., xvi. (1882) pp. 537–42, 640–9 (2 pls.).

senting at least 28 species. Seventy-six were Entomostraca of 20 species. Nearly three-fourths were Cladocera. One-third were *Acroperus leucocephalus* Koch.

Vermes.

Development of Annelids.* — Professor W. Salensky gives an account of his own observations; in dealing with marine forms, he studied among others a species of *Terebella*, *Nereis cultrifera*, and *Spio fuliginosus*. In all that he studied he found cleavage to be unequal, and to lead to the formation of an amphigastrula; before the division on the surface of the egg lively protoplasmic movements were always observed in *Spio*, the protoplasm giving rise to lobate, clear, pseudopodia-like processes, which altered in form during the whole process of division, and at its conclusion were withdrawn. The first rudiment of the mesoblast appeared to arise from the micromeres of the second cleavage; in some other cases the mesoderm appeared in the form of two primitive mesoblasts lying near the edge of the blastopore; in *Psygmobranchus* the primitive endodermal cells do not represent the whole endoderm, for they only form the dorsal portion of the nutrient cavity, while its ventral wall arises from a collection of cells on the ventral surface (secondary endoderm). The author finds that the mode of formation of the mid-gut is different in the forms examined by him; in *Nereis dumerilii* Goette found that the endoderm arose from the four large endodermal cells, in the form of a ventral cord of cells, while the four (and later) five large fat-containing cells were pressed forward and dorsally, and used as nutrient yolk. In this arrangement the author found *Psygmobranchus* to agree more closely than *N. cultrifera*. Differences were observed in the origin of the fore- and hind-guts, which in *Psygmobranchus* and *Aricia* had an endodermal, and in *Nereis* an ectodermal origin. Striking as this difference would appear to be, it was found to be really more quantitative than qualitative; and the endodermal origin is to be regarded as nothing more than the result of an incomplete ectodermal invagination.

Greater similarities were noted in the mode of development of the nervous system; and the results of Kleinenberg and other later investigators as to the independent origin of the supra-œsophageal ganglion and the ventral ganglionic chain were confirmed. It was noted that a cord-like process always extended from the lower surface of the frontal plate to the subjacent mesoderm; and these were regarded as being homologous with the cords which, in vermian larvæ provided with mesenchymatous cells, form the rudiments of these cells. After discussing the characters of the ventral ciliated groove, Salensky states that in not very young larvæ of *Psygmobranchus* he observed, between the epithelium of hind-gut and the "Darmfaserblatt," a cavity filled with clear fluid; the wall of the cavity was contractile and exhibited regular pulsations, by means of which the fluid was driven forwards. In *Terebella*, likewise, the formation of the blood-vessels is preceded by such a perigastric

* Biol. Centralbl., ii. (1882) pp. 198-208.

cavity, whence the enteric vessels are derived. It is important to note that in the lower Annelids (e. g. *Protodrilus leuckarti*) there is permanently some such arrangement of the blood-vascular system, while, further, we are shown that at first the blood-vessels have nothing to do with, but are completely independent of, the lymphatic spaces (cœlom, &c.).

In *Branchiobdella* the ova, like their parent, are to be found in the gill-lamellæ of the crayfish; they are of some size and are covered by a hard shell, produced posteriorly into a small stalk of attachment. There is very early a difference between the appearance of the dorsal and ventral surface, and cleavage obtains much more rapidly among the cells of the latter. The endoderm and mesoderm are formed by the division of the macromeres, which constantly extends from behind forwards; no primitive mesoblasts were detected. Soon after the formation of the layers a small depression appears on the dorsal surface, the significance of which could not be made out, though it was possibly the rudiment of the supra-œsophageal ganglion. Soon after the appearance of this depression there appears on the ventral surface a large groove—the *neural* groove; this is pyriform in shape, the broader end being posterior, and the narrower anterior end having a T-shaped enlargement. At first, the groove consists of a layer of flattened cells, which are not to be distinguished from the other ectodermal cells; they soon, however, increase in number, and the groove itself is thereby narrowed and flattened out, till it becomes converted into a tube—the *neural* tube. About this time, the hinder portion of the embryo also becomes altered; the cells which were arranged in two rows divide, and the hinder part gives rise to two median ridges, which correspond to the germ-stripes of other Hirudinea. Segmentation commences early, and, after it has commenced, the embryo undergoes a series of changes, in consequence of which the dorsal surface ceases to be, and the ventral becomes convex. Prior to the formation, which is somewhat late, of the cœlom there is a cavity on the dorsal surface between the ecto- and endoderm; this is generally anterior in position, and may be spoken of as the primary cœlom. The oral invagination of the ectoderm gives rise to nothing but the inner lining of the lips, all the other parts of the mouth and its region being endodermal in origin.

Development of the Central Nervous System of Annelids.*—It is pointed out by J. W. Spengel, in an account of Kleinenberg's recent researches on this subject, that we have here to do with the development of new structures in the course of phylogenetic development. The special larva studied appears to have been *Lopadorhynchus*, which is of the Lovenian type. Simple as are most of the organs of this form, the ectoderm presents considerable histological differentiation; a strong nerve lies in the groove formed on the ciliated girdle, and this nerve is circular. On the upper hemisphere of the larva the ectoderm is found to consist of large elements, immediately below

* Biol. Centralbl., ii. (1882) pp. 231–6.

which we find a small but deep pit in the ventral middle line.   The cells around the pit are small and spindle-shaped, or are large and branched, and call to mind isolated ganglion-cells.   The latter do not touch the surface, but are completely shut off from it by other ectodermal cells.   All these form the first rudiment of the preoral nervous apparatus of the larva.   On the lower hemisphere of the larva part of the ectoderm is, again, composed of as large cells as some of those in the upper hemisphere, and these are found in a ventral triangular area, the apex of which is turned towards the anus.   This area is divided by a groove into two symmetrical lateral halves.   On either side there is a thickened ectodermal band, the so-called ventral germ-band.   From this there is gradually separated off a lower layer which forms the definitive mesoderm, while of the remainder the median portion gives rise to the ventral nerve-cords.   Before these series of differentiations have been completed the ganglion-cells of the upper hemisphere have, by means of their processes, become connected with one another, and have thus given rise to a kind of plexus.   Some, however, of the small spindle-shaped cells have by their processes become closely fused with the fibres of the nerve-ring, and a transverse commissure has been developed by the anastomoses of the cells on either side of the hemisphere.   We have now, therefore, got a semicircular loop which extends over the ventral surface of the upper hemisphere, and passes by its ends into the nerve-ring.   Just about this time a connection is also established between the nerve-cords in the lower hemisphere and the circular nerves.   As this takes place at the point of formation of the anterior commissure, we find that the rudiments of the cephalic ganglion and of the ventral ganglionic chain are at first connected with one another by the intermediation of the circular nerves.

Kleinenberg compares this nerve-ring in the polychætous larvæ with the nerve-ring of the medusæ, and speaks of the upper hemisphere of the worm-larva as the umbrella, and the lower as the sub-umbrella.   But if the nerve-ring is the nervous system of the larva, then it has no homologue in the developed worm.   " We see, therefore, in the cycle of the ontogenetic development of one animal an organ of the same physiological significance appearing twice over, and as being formed on two different types.   The larvæ of Annelids possess the old nervous system of the Cœlenterata, while the Annelids themselves have their own proper central organs, which are in no way modifications of the other.   The organ of the lower type is developed, and is functional in the larva, but in the adult it is replaced by a fresh formation."

In explanation of this remarkable modification, Kleinenberg points out that variations have a definite character, which, though dependent on external activities, must also be conditioned by the characters of the form itself.   The mere development of any new organ must be accompanied by changes within, though perhaps not without, the organism.   There is a limit, as it were, of equilibrium to variations, but this limit may be passed if the change is of advantage, and then we find considerable modifications in the organism itself.   The

development of a nervous organ must result in a rearrangement of all the organs of the body, and may affect indifferent tissues. When this happens new structures arise, which will owe the direction they take to the organ that has caused them, which probably will itself become larger and more complete. The formation of a central nervous organ will cause a change not only in the already developed peripheral nervous system, but in a number of indifferent ectodermal cells, which will take on a nervous character and become united into new organs. This process may be called that of substitution, and is not to be confounded with change of function, or with the process of the physiological division of labour.

Applying these considerations to the Annelids, and starting from the Cœlenterata, we find in the Annelid larva a nerve-ring and a sensory epithelium. The organs of the latter gradually took on the functions of the old nerve-ring, and became converted into more independent organs. As the function of the primitive central organ disappeared it became suppressed, and is only seen now in the organization of the larva. The notochord and vertebral column of the vertebrata probably afford another example of this process of substitution.

Coral-reef Annelid.*—The Rev. T. Powell gives an account of the structure and habits of *Palolo viridis,* in which he states his reasons for considering as inaccurate the notion that the animals break up into small pieces in order to effect the liberation of the eggs and of the sperm. Their sight is evidently perfect. The time of their appearance is the day of the last quarter of the moon in each October, unless that fall at the beginning of the month, in which case another lunar month will intervene. This indicates that the moon exercises some mysterious influence on their reproduction.

Muscular Tissue of the Leech.†—T. W. Shore finds that—1. The muscle of the leech consists of elongated tubes with two coats—a sarcolemma and contractile layer—the inner surface of which is irregular, and gives rise to apparently granular contents. 2. In the living condition it is unstriped. 3. There are no nuclei. 4. Transverse striation may be produced post-mortem, the result of three changes : — α. Regular arrangement of the papillæ on the inner surface of the contractile layer. β. Folding of the surface of the sarcolemma. δ. Splitting into segments of the contractile substances which subsequently contract. 5. The contractile substance coagulates, forming myosin, which subsequently contracts. 6. The rapidity of contraction gives rise to varying appearances of fissures, striations, &c.

Observations on the Dicyemidæ.‡ — E. van Beneden gives us the result of some further studies on these important forms. He commences by describing two new generic types, the first of which, *Conocyema polymorpha,* lives with *Dicyema typus* in the renal cavity of *Sepia officinalis.* It is not, however, nearly so common as its com-

panion, but here, as elsewhere, two kinds of females can be distinguished—the nematogenous and the rhombogenous. The former have a body of very variable external appearance; it may be elongated, irregularly rounded, claviform, much swollen at one extremity, or attenuated at both. Four granular lobes can always be distinguished, and these, although they vary much in form in different individuals, are always formed of a single cell, just as are the two lobes in *Dicyema*. As in other Dicyemidæ, there is a cortical layer and an axial or medullary body. The former is made up of a small number of epithelial cells, set in a single layer, and so touching one another as to form a continuous membrane, which completely shuts in the medullary portion. Each cell is ciliated in youth, and smooth when adult. It is not possible, as in *Dicyema*, to distinguish polar and parapolar cells, there being no cephalic tuft. As may be supposed, the medullary body consists of a single cell. In this there are to be found germs and embryos at every stage in development. It varies greatly in form, but is always limited by a firm layer of protoplasm, of equal thickness throughout its whole extent, and always capable of allowing of the passage of the contained embryos. The nucleus is generally oval, has a distinct limiting membrane, and is traversed by a nucleoplasmatic reticulum.

When the embryo is on the point of leaving its parent it presents a convex and almost hemispherical hinder face. It is about one and a half times as long as it is wide, and a short way from the anterior end there is a circular constriction which has sometimes the appearance of a rather deep groove. It is covered by vibratile cilia, by the aid of which it swims freely in the liquid of the *corpus spongiosum*, when it has made its way out of its parent, and in thus moving it describes a spiral. The cuneiform embryo of *Conocyema*, like the vermiform one of *Dicyema*, has a large central cell, and a peripheral epithelial investment; but while in the latter it is always fusiform or cylindrical, it is here always spherical. Among the outer cells the four apical ones may always be distinguished. The embryos, with these characters, are all developed from monocellular germs, which have all the signs of true ovules. These divide into two, and then into four blastomeres, one of which is often very much larger than the rest. In the next stage there are six small and one large cell, and then we have an epibolic gastrula. The six smaller outer cells dividing, we get thirteen in all, which is the number characteristic of the adult. The cuneiform embryo escapes to the exterior by perforating the body of its mother, the four apical cells become charged with granules, the axial cell becomes enormously developed, and new germs appear.

After pointing out briefly the characters of the rhombogenous form, Professor van Beneden passes to *Microcyema vespa*, the small embryo of which was taken by G. Wagener for the infusoriform embryo of *Dicyema gracile*. It is divided into two parts by a median constriction; the hinder of these consists of an axial fusiform cell, and of two others which completely envelope it. The anterior end of the central cell projects into the anterior segment, where there is also a granular mass and a cortical layer, formed of two clear cells similar to those

which are found in the hinder segment. The parent is tubular in form, slightly enlarged at one end, completely smooth, with a delicate cortical layer. Transitional forms between these two stages were observed, and it was found that the anterior tuft of cilia on the embryo disappears very early. The author thinks himself justified in regarding this form as a distinct generic type.

As has been pointed out by Huxley, we cannot form any definite opinion as to the affinities of these forms until we know something more about the characters of the infusoriform embryo; Van Beneden believed that this form might be the means by which the parasite passed from one to another individual Cephalopod, but the researches of Metschnikof and Julin on the history of the Orthonectida have largely destroyed that hypothesis, and now give rise to the question whether the infusoriform type is not the mature male, and its " urne " a testicle ; to see if this view could be confirmed the author closely examined them in the hope of detecting spermatozoa, but in vain. On the other hand, we now know that the spermatozoa of the Orthonectida are very small and very difficult to see. Too much weight must not, therefore, be given to this negative result. And the hypothesis which suggested the investigation commends itself, on many considerations, to the author's mind.

When the first studies on the Dicyemidæ were published, the absence of any mesoderm was insisted on ; since that time, and chiefly, thanks to the researches of the brothers Hertwig, it has been allowed that the mesodermal formations in the Metazoa have not all the same anatomical value. Still, it remains true that the Dicyemidæ have neither mesenchyma nor cœlomic folds. This being so, we find in this important fact a justification for the establishment of a phylum of *Mesozoa*. These may be defined as " organisms formed of two layers, the ectoderm of a layer of more or less ciliated cells, the endoderm of a single or of several cells. The sexual products arise from the endoderm. There is no mesenchyma, cœlomic folds, or any fundamental lamella ; two female forms, one arising exclusively from the males, the other from the females. All the Mesozoa actually known are parasites." They are divisible into the Orthonectida and the Rhombozoa ; the former have the body composed of several rings and the endoderm of several cells, some of which take on the epithelio-muscular type, and give rise to muscular fibrils, while the others form the sexual products. The male is elongated, and the female oviparous. The Rhombozoa, which are divisible into the Dicyemida and Heterocyemida, have the body annelated, the endoderm formed of a single cell, no muscular fibrils. The male is peg-top in shape, refractive bodies are found in some of the smooth anterior cells, and the females are viviparous.

The author discusses the question as to whether the Mesozoa are Metazoa degenerated by parasitism, and specially the doctrine of Leuckart,[*] that they are comparable to the ciliated larvæ of the Distomata. He points out that the resemblance is chiefly external, and that a *Dicyema* is much more like a *Planula* or a *Gastrula*, and

* See this Journal, *ante* p. 343.

2 u 2

that, further, the ectoderm never gives any indication of the development of an intermediate layer. In examining the question of the homology of the medullary body of *Rhopalura* or *Dicyema* with the endoderm of a Metazoon, it is shown that in their earlier stages of development all the forms agree closely with one another, and if we allow that the inner layer (endoderm) is homologous throughout the whole of the Metazoic series, we can find no good reason for shutting out the endoderm of the Mesozoa. Certainly no supporting fact is to be found in the absence of a digestive cavity, as the Acœla, among the Rhabdocœla, with their intracellular mode of digestion, are alone sufficient to demonstrate.

Orthonectida.[*]—C. Julin here gives a full account of his researches, to the preliminary notice of which we have already referred (p. 511); he is of opinion that the Orthonectida cannot be considered as triploblastic forms or Metazoa, but as Mesozoa or diploblastic forms, the muscular layer which is developed not being a formation of a mesoderm, but only a histological differentiation of the endodermic cell; so far they resemble the Actinozoa, but they are distinguished from them by the fact that the muscular cells do not, throughout the whole of their life, remain connected with the endoderm. When we compare them with the Dicyemidæ we find various points of resemblance, (1) Just as in them there are nematogenous and rhombogenous forms, so in these there is a flattened form which gives rise only to female embryos, and a cylindrical form whence develope the males, and the two female forms are to be found in the same host; (2) the gastrula in both groups is formed by epiboly; (3) the structure is essentially the same in the two—a ciliated ectoderm, differentiated into a cephalic region at the anterior pole, and an endoderm of one or of several cells; the difference in this last character is due to the different mode of formation of the germs; in the Orthonectida they arise by division of the primitive endodermic cell, and in the Dicyemida by an endogenous process. The views of Giard and Metschnikof that the Orthonectida may be compared to the Turbellaria, are objected to chiefly on the ground of the great development of the mesenchyma in these lowly worms; the doctrine that they have degenerated under the influence of the parasitic habit is not confirmed by the history of their development, in which they exhibit no traces of any higher organization.

Julin regards the Mesozoa as pluricellular organisms, composed of two kind of cells, ectodermal and endodermal, without any trace of any mesenchyma, cœlom, vessels, muscles or nervous tissue of mesodermic origin; they are developed by the division of the egg-cell and its differentiation into a peripheral and a central layer. He insists on the incorrectness of the use of the term metamere or segment as applied to these forms, pointing out that the appearance which has induced some authors to apply these expressions is due only to the presence at certain points of shallow grooves between the transverse rows of ectodermic cells, there is no internal segmentation corre-

[*] Arch. de Biol., iii. (1882) pp. 1–54 (3 pls.).

sponding to this appearance, and in some cases a large number of females may be seen to be without it altogether. A more proper term would be "ring" simply.

It is not easy to detect when an Ophiurid is infested by these parasites, but as a rule such specimens have a more greyish tint, their tissues appear softer, and their movements are less rapid; as a rule one in twenty *Amphiuræ* were found to contain Orthonectids; the observation of Metschnikof that a consequence of their presence is an atrophy of the genital glands, has been verified by Julin.

An adult male is 0·104 mm. long, the body fusiform and elongated, and a little drawn out at either end, there are generally six rings, the cilia on the first (head) are directed forwards, and on the rest backwards; the spermatozoids are contained in a structureless pouch, and when mature may be seen moving about rapidly within it; when the wall of the pouch bursts they escape between the muscular fibrils, which separate from one another so as to form a cavity, bounded externally by the ectoderm; the cells of this layer undergo change and some become detached, and the male products are then able to make their way to the exterior; at the same time it may be seen that the muscular fibrils undergo atrophy.

The cylindrical form of the female is 0·280 mm. long, is fusiform and has generally eight rings, the first and last of which are formed by a large number of small ectodermic cells. The flattened form of female is 0·250 mm. long, has wide ventral and dorsal surfaces, and narrower sides, the grooves are so shallow that it is impossible to count the number of the rings, and the whole surface is covered with cilia; this form was regarded by Metschnikof as being immature, but the presence of ova is not in support of that view, which is more completely contradicted by the differences between its history and that of the cylindrical form; the flattened forms appear to break up into fragments, and the ova, instead of being free, are kept united together to form more or less regular masses, limited externally by a ciliated epithelial layer derived from the ectoderm of the adult. As has been already stated, there is a difference of sex in the products of these two female forms. As to the question of parthenogenesis, which is raised by some observations, the author does not yet feel himself able to speak confidently.

New Rotifer (Cupelopagis bucinedax).*—Mr. S. A. Forbes describes a new Rotifer as follows:—

Cupelopagis gen. nov. Footless, eyeless, without carapace, and totally destitute of cilia or other vibratile structures, or locomotor organs of any kind. The trochal disk has the form of a large, oblique cup, which can be either retracted wholly, or pushed up by a constriction of its wide mouth. In the bottom of this cup is the oral aperture, which opens into a very large, loose crop, at the bottom of which, and usually behind the middle of the body, is the mastax. The jaws, which project into the crop, are composed of two sharp, slender hooks, with about four slender, straight teeth at the inner base.

* Amer. Mon. Micr. Journ., iii. (1882) pp. 102-3 (1 fig.).

The stomach is large, and the intestine very small and short, opening on the ventral surface of the body near the posterior end.

C. bucinedax sp. nov. The body is a coriaceous, flattened sac, minutely roughened over the whole surface, nearly as broad as long, and about three-fourths as thick. The dorsal outline is longest and strongly convex, the ventral being usually somewhat concave. The cup is oblique, the ventral height being a little more than half the dorsal. Its lower wall usually presents a shallow, longitudinal cavity, so that the aperture is slightly kidney-shaped. The surface of the cup is more delicately roughened than the body, and its edge is minutely erose. In the average specimen the length of the body, without the cup, was 0·016 inch, and its width 0·014 inch.

This rotifer has no means of attracting its prey or bringing it within reach, but depends wholly on such animals as chance to swim into its oral cup. When a *Stentor* or other animalcule of considerable size enters the trap, the rotifer quickly pushes up the aperture and contracts the walls of the cup upon it, until it is forced, with a sudden slip, into the ample cavity of the pharynx. This apparatus enables it to secure much larger prey than the usual ciliated structure; but, in the absence of locomotor organs, it can only live in water swarming with suitable food. In the aquarium in which it was found it was living almost wholly on the large Stentors.

The author adds * as the result of a communication from Dr. J. Leidy, that *Dictyophora vorax* described by him,† is evidently closely allied and probably belongs to the same genus. The name is, however, preoccupied.

Echinodermata.

Anatomy of Echinoids.‡—R. Koehler finds that the Polian vesicle of regular Echinoids has the structure of an excretory organ; he describes them as being, to the naked eye, of a light brown colour, which is due to the presence of small brown lines which pass from the middle line to the periphery of the organ, becoming wider as they do so. The two layers of connective tissue, which form the walls of the organ, are so united that the space between them consists of small cavities, filled with special elements; these last are cells with a very distinct nucleus, and their protoplasm gives off fine prolongations, which extend from one cell to another. In addition, there are numerous granulations, arranged in masses and cubical cells, the nature of which could not be made out. On the whole, there is much resemblance to the excretory organ of *Spatangus*.

The author describes the pedicellariæ of *Dorocidaris papillata*, and directs especial attention to the presence of the small gemmiform ones on the buccal membrane, where they have never yet been recorded. "Five very curious appendages" are described in connection with the lantern of Aristotle, which are no doubt the gill-

like organs of C. Stewart. Of the four kinds of pedicellariæ in *Schizaster canaliferus* one is tetradactyle; in this form there are only two pairs of genital glands, and the sand canal does not follow its usual complicated course. In *Brissopsis lyrifera* the author notes a narrow canal which he looks upon as being a second "siphon," and, in conclusion, he states that while his observations have led him to see only slight modifications in the details of the anatomical structure and arrangements of the internal organs of regular Echinoids, he finds that in the irregular forms the internal organs have, in their differentiation, followed the migrations of the branches, which commenced in the Jurassic period and appear to have profoundly affected their primitive structure.

Anatomy of Spatangus purpureus.[*]—R. Koehler has studied the circulatory system of this Echinoid. He finds that the branch described by Hoffmann, connecting the intestinal vessel with the perioral ring, bifurcates at the level of the mouth, and sends one branch to the blood-vascular ring and the other to the ambulacral ring. The sand-canal is double between the mouth and the end of the œsophagus; it remains single from this point up to the second curvature of the alimentary canal, and after this is divided by septa into several secondary chambers, up to the point where it opens into the "heart"; on the opposite side of that organ it becomes a narrow tube. The so-called heart is spongy, and its cavity is in direct connection with that of the sand-canal; it consists of connective tissue, provided with numerous nuclei and cellular elements resembling those of the blood; the membrane which attaches the sand-canal to the madreporic tubercle has a similar structure, and perhaps both organs are glandular, and discharge either excretory or blood-vascular functions. The blood-vessels of the alimentary canal are derived from the external and internal marginal trunks, but the œsophagus, the 3rd curvature, and the rectum, are quite devoid of vessels. Most of those on the 2nd curvature occur on its dorsal surface, the only ventral vessels in this region being found near the orifice and on each side of the diverticulum. The intestinal vessel of Hoffmann does not reach the stomach. The vessels of the latter consist of a very close plexus formed around the opening of the diverticulum by the two marginal vessels and of vessels derived from this plexus, and extending along each side of the stomach as far as the siphon and connected by transverse tubes both on the anterior and posterior sides. The right-hand branch sends twigs to the mesentery between the diverticulum and alimentary canal. All these branches re-unite into a trunk which follows the course of the diverticulum up to the heart.

Over the vascular parts of the digestive canal the epithelium is thicker and composed of larger and longer cells than the non-vascular parts. This epithelium is made up of several layers of cells, the deepest being rounded, small, closely appressed, the superficial ones very long, 10 or 15 diameters in length; below it is a delicate continuous elastic membrane. The connective tissue behind the membrane forms

two distinct lamellæ; the outer is dense, of equal thickness throughout, and remarkably refringent; reagents bring out in it the appearance of fine undulating fibrils; the inner layer is loose, with wide fenestræ, and contains numerous cells and brown or yellow pigment-granules; it is in the latter layer that the blood-vessels ramify; in the non-vascular parts it is thicker, except on the rectum. The alimentary canal is provided with glands of two different types, viz.:—(1) Mucus-cells; large, oval, very numerous, placed among the epithelial cells; they occur in the second curvature, especially at its vascular parts. (2) Glands proper; they are pyriform and multicellular, the component cells radiating from the centre of the gland; each gland opens separately into the intestine, and lies in the loose inner layer of the connective tissue, but only in the region between the first opening of the siphon and the end of the œsophagus. The nerve-ring surrounding the mouth is quite distinct from the blood-vessels, and is not embraced, as has been stated, by one of the latter. A further examination of the "heart" confirms the view of its glandular nature; it is broken up by trabeculæ into a number of cavities, containing cellular elements of two kinds, viz. either regular cells with distinct outline and tolerably refringent protoplasm, or cells with very irregular and indistinct outlines, with transparent but scanty protoplasm and granular nuclei, often two or three in number in the same cell; with these elements occur also brown or yellow granules, some of the yellow ones being aggregated into strawberry-like masses. Injection of the heart by way of the sand-canal shows that it communicates both with the madreporic plate and with the spaces of the connective tissue, and of the body generally; thus the blood probably undergoes some modification in the organ, and is then in part carried into the general system and in part thrown off from the body,

In *Echinocardium flavescens* the internal marginal vessel and the siphon are a little longer than in *Spatangus*, and they terminate at the point of junction between the second and third bends of the alimentary canal. This form also differs from *Spatangus* in possessing a small diverticulum or fæcal reservoir in the rectum.

Development of Asterina gibbosa.[*]—Professor H. Ludwig finds, as a general result of his important studies, that we have throughout the Echinodermata a mode of development which must be spoken of as a metamorphosis; the ground-form of the larva is an organism ciliated over the whole surface, with a mouth and anus on one side. By adaptation to different conditions of existence this ground-form has become variously modified as *Bipinnaria, Pluteus,* &c., which may be known as the secondary larval forms. The mature Echinoderm-form may arise either directly from the primary larva, or from a secondary larval form; or, further, one secondary larval may be followed by another larval form (e. g. *Bipinnaria, Brachiolaria*); but this interpolation of intermediate stages makes no essential difference in the course of the development. The processes by which the

[*] Zeitschr. f. wiss. Zool., xxxvii. (1882) pp. 1–98 (8 pls.).

primary larva is converted into the Echinoderm appear to be essentially the same in all cases; all that happens in a more complicated history being the fact that in the secondary larvæ there is an absorption of those larval parts which had themselves become secondary. The secondary characters are not to be regarded as having anything to do with the future organization of the Echinoderm, but as adaptations, proper to the larval life, and disappearing with its cessation.

After giving a description of the mode of attachment of the eggs by the female, and the mode of fertilization, the author states that the two first cleavage spheres are almost equal in size ; differences, however, soon become apparent since one divides before the other. The results of cleavage are, not a solid morula, but a blastosphere with a unilaminate wall; the gastrula is formed by invagination. The absence of a morula would appear to be a constant phenomenon among the Echinodermata, and no other mode of formation of the gastrula than that by invagination has ever yet been observed. The mesoderm would appear to be generally derived from the endoderm, the cells wandering in the fluid of the blastocœl : some share, however, is taken by the ectoderm, and it may be perhaps justifiably supposed that this mesoderm presents indications of a bilateral symmetry.

The gastrula-enteron is composed of two chief portions, a short cylindrical entrance, and a spacious vesicular terminal part; from the latter we have developed the enterocœl, the first signs of which are the appearance of an out-growing process on either side, the enterocœlic pouches. All this region is to be considered as being essentially nothing more than a vesicular enlargement of the blind end of the primitive intestine. Up to and at this time the structure of the larva is still in all points bilaterally symmetrical; but this symmetry soon begins to disappear, the enterocœlic pouches are no longer of the same size, owing to the much greater development of the left one. The external form also becomes altered, and on the fourth day there appears at the centre of the anterior side a depression of the ectoderm, which is the rudiment of the mouth and stomodæum of the larva. Towards the end of the fourth, or on the fifth day, the enterocœl becomes completely shut off from the larval enteron and the larval stomodæum opens into this latter. During the fifth day the rudiment of the water-vascular system becomes developed from the left enterocœlic pouch, and this outgrowth may be conveniently spoken of as the *hydrocœl ;* connected with it are the rudiments of the five primary vessels of the water-vascular system, which first appear as five slight outgrowths. Contemporaneously with the development of the hydrocœl we have the formation of the dorsal pore of the larva, which is due to an invagination of the ectoderm, which becomes connected with the left enterocœlic pouch. With the exception of the observations of Kowalevsky on *Psolinus brevis*, the evidence of all embryologists would lead us to suppose that the history given of the hydrocœl of *Asternia* is generally true of all Echinoderms. The author is inclined to look upon the dorsal pore, in its primary relations, as being a pore which led into the

enterocœl, and that its connection with the hydrocœl, therefrom developed, is only a secondary phenomenon ; this earlier relation is retained by the Crinoidea, where the primary pore opens into the enterocœl. After discussing the further development of the hydrocœl, and the history of the blood-vascular system and permanent stomodæum, the author passes to a description of the external form of the larva, where attention is directed to the so-called " larval organ," or two cephalic lobes, the one smaller and anterior, the other larger and posterior, which form a special locomotor organ and are at the height of their development from the seventh to the ninth days. The wall of this organ consists of the three layers of the body, fine muscular fibres being developed on the outer side of the endodermal layer ; the cavity of the organ is a development of the enterocœl, and the whole structure may be looked upon as being the homologue of the arms of a *Brachiolaria*.

In an account of the development of the skeleton it is necessary to distinguish two groups of skeletal parts, both of which appear early ; to one are due the rudiments of the ambulacral pieces of the future arms, and to the other those of the primary skeletal pieces of the dorsal side of the starfish. A detailed study of the former shows that they arise in just the same way as in Ophiurans ; the latter are developed in the mesoderm of the body wall, and on the seventh day eleven pieces may be made out ; one of these always has a remarkably constant relation to the dorsal pores, and is the one which becomes converted into the madreporic plate ; the pore does not primitively lie in the plate, but to the left of it ; this relation is of significance when compared with what is seen in other Echinoderms ; in Ophiurans the pore lies towards the left margin of the plate, and in Crinoids the primary pore has a similar relation to one of the oral plates. The other ten pieces do not all arise together, or exhibit the same rate of growth ; five of them are the rudiments of the so-called " radialia," or better, " terminalia " of the arms of the starfish ; within and alternating with them lie the primary interradial plates, one of which forms the madreporite ; the eleventh piece occupies a more central position and is the rudiment of the central plate of the back.

As the larva derived from the gastrula gradually passes into the young sea-star, the larval organs become lost, the " larval organ " and the stomodæum of the larva being the last to be retained. On the ninth day, however, the larval organ decreases in size, till on the tenth or eleventh it forms nothing but a short stalked and knobbed process. This is doubtless the peculiar peduncle noted by Desor in a species of *Echinaster*, and corresponds to the different structures to which L. Agassiz, Wyv. Thomson, and Philippi have directed attention. After describing the history of the enteric tract, and especially the mouth, the author raises the question of whether there is a plane of symmetry in the young corresponding to the median plane of the larva ; he thinks that none is to be, or indeed can be, detected ; want of symmetry is one of the leading characters in Echinoderm structure ; yet this asymmetry is ordered by definite laws. If any radius or interradius is to be regarded as the " anterior " one, it must be that

interradius in which is placed the remnant of the larval organ, and is at the same time the anal interradius; when the larval organ and arms are both lost it may still be recognized by the fact that the madreporite lies just to the left of it, in a dorsal view.

Attention is next directed to the nervous system, which had originally the form of an annular ridge encircling the point at which the mouth is afterwards developed; the epithelium above the radial water-vessels thickens, and the radial nerves are developed from its lower layers; the rudiments are developed in an adoral and aboral direction, but before they reach the tentacles they swell out to form the eyes.

Ludwig looks upon the ambulacral plates of Echinoids as being homologous with the adambulacral plates of the Asterid and the lateral plates of the arms of the Ophiurid; the primary interradials are homologous with the genital plates of Echinoids, and the five pairs of plates which are found on the actual edge of the interradials of the starfish correspond in position to the paired interambulacral plates of Echinoids, and so represent a first pair of interambulacral plates; the so-called odontophore which the author previously took to be an intermediate piece, is now regarded as an unpaired interambulacral plate.

In conclusion attention is directed to the corm-theory of Echinoderm structure which has been revived and pressed by Professor Haeckel, the author considering that no support for it is to be found in the developmental history of any Echinoderm.

Brisinga.*—Professor E. Perrier has some notes on this interesting starfish, based on a study of sixteen well-preserved disks, two young, and a large number of perfect, though single arms, in addition to a magnificent specimen which was almost complete. Such a series has, first of all, led him to the view that *B. coronata* and *B. endecacnemos* are only two forms of the same species; on the other hand, a new form, *B. edwardsii* has been dredged in the Atlantic; in this the arms are covered by imbricated plates, without spines. It is pointed out that in *Hymenodiscus* the whole skeleton is reduced to the ambulacral and adambulacral pieces, which, therefore, must alone be regarded as the essential parts of an Asterid. In *Brisinga* we have in addition, parts of the dorsal skeleton, which are arranged in arches, more or less closely set; these are, however, only found in the swollen part of the arms, where the genital glands are developed, and they are not to be seen in the young where the glands are still rudimentary; this set of plates must, therefore, throughout the whole Asterid series, be looked on as an apparatus specially applied to the purpose of protecting the reproductive glands. The disk of *Brisinga* is formed early in life, around a digestive sac, the prolongations of which are only developed later on; these different facts appear to support the doctrine the author has already taught, that the Echinoderm, like the Medusa or the Coral, is the result of the fusion of reproductive individuals around a central nutritive one.

* Comptes Rendus, xciv. (1882) pp. 61–3.

In the young the disk consists of one central and nine large contiguous triangular pieces, some of which are interbrachial, and all of which carry large mobile spines, together with a few smaller plates, which alternate with these latter and are intermediate between them and the central piece, but considerable changes occur during growth; the central pieces become separated, the interbrachials are pushed to the edge of the disk, and, becoming placed exactly in the angle of the arms, they end by forming the odontophores. The madreporic plate is always formed on one of the plates of the first row of the disk; in *Brisinga* the forcing out of these plates stops when they reach the outer edge of the buccal ring; if the process of growth had only continued and carried all these pieces on to the ventral surface, we should have had an Asterid with the ventral surface of an Ophiurid. Here then we see a considerable "rapprochement" between Ophiurids and Asterids, while the earlier arrangement of the plates of the disk seems to M. Perrier to recall the constitution of a Crinoid.

Anatomy of Holothurians.[*]—E. Jourdan describes the testicular tube as being formed of three layers; an external cellular investment, a fibro-muscular zone, and a layer of internal epithelium. In *Holothuria tubulosa* the majority of the cells of the first of these are large and flattened; some, however, are distinguished by consisting of a mass of refractive corpuscles within a delicate membrane; these are feebly coloured grey by osmic acid, and are strongly coloured by methyl-green; the latter fact would lead one to suppose that they were young cells, while in their general appearance they are to be compared to fat-cells. In *Cucumaria* and *Phyllophorus* the cells of this layer can in no way be compared to ordinary epithelial cells; and it would seem to follow that in some genera of Holothurians the peritoneal elements have acquired a special importance, inasmuch as the normal epithelial cells have completely disappeared. In the median layer we find a connective membrane overlaid by a layer of very fine circular muscles, identical with those which are to be found in the Polian vesicle.

The study of the internal epithelial layer ought not to be separated from that of the spermatozoa; the sperm, if examined in spring or summer, is found to consist of a mass of large cells which may be regarded as spermatoblasts; the cells of these bodies are similar to those which line the walls of the testicular tubes, and are found, when isolated, to be identical with them. Cells, likewise spherical, are also to be made out in which the protoplasm appears to be condensed into a very large nucleus, while first one, and then several, homogeneous refractive corpuscles appear in the spermatoblasts; the granular protoplasm at last disappears altogether, and in the place of the original spermatoblast we have a cell containing a number of corpuscles, each of which represents a spermatozooid; these have, when developed, a spherical head and a very long tail.

It has been found that each tube of the so-called Cuvierian organ consists of a muscular sheath formed of bundles of longitudinal and a

[*] Comptes Rendus, xcv. (1882) pp. 252-4.

layer of circular fibres ; in the centre there is a mass of folded and spiral fibres, and in the axis of each tube there is a narrow, irregular canal, lined by cells containing granular protoplasm. By the contraction of the muscular sheath the animal forces to the exterior the connective elastic mass within each tube ; these become agglutinated with all the bodies with which they come into contact.

Cœlenterata.

Tissues of Siphonophora.*—C. Chun, in his second paper,† adds some facts as to the nervous system ; he finds that the richly branched ganglionic cells on the upper surface of the disk are connected with one another by their terminal processes, in addition to which triangular connecting plates are developed at the points of division. Exceptionally large ganglion-cells lie on the radial muscular fibrils, and give rise to a kind of nerve-ring. Ganglion-cells are also to be found on the inner or chitin-secreting lamella of the ectoderm, but they are not so richly branched or so large ; similar cells have been detected in the ectoderm of the air-sac, and the gastric polypites of *Rhizophysa*, and in the gastric polypites of *Physalia*. In these forms the ganglion-cells pass inwards, but in the ectoderm of the tentacle of *Apolemia uvaria* they remain superficial. As yet the author has failed to find nervous cells in the transversely striated musculature of the nectocalyces of *Diphyes*, where they might naturally be looked for ; at the same time it was found on experiment that stimulation of one nectocalyx is carried over the whole colony.

Ciliated and glandular cells are widely developed in the ectoderm ; the tentacular appendages at the base of the fishing-tentacles of *Physalia* are invested thickly by stinging-cells, among which long supporting and numerous glandular cells are to be made out. The supply of mucus in the Velellidæ may be supposed to take the place of the absent fishing lines.

The arrangement of the musculature which obtains in the Siphonophora would appear to be that which is found in most Hydroids ; there are longitudinal fibres developed from the ectodermal epitheliomuscular cells, and transverse, or circular, endodermal muscular fibrils ; the latter system would appear to be best developed in the air-bladder of *Physalia*, where in addition to the muscles ganglioncells may be made out.

Structures called ciliated funnels are described as being found in the endoderm of the middle third of a tentacle of *Apolemia uvaria ;* there may be seen three endodermal longitudinal ridges which can be followed almost to the tip of the tentacle ; they consist of non-ciliated mucus-cells, with, on the surface, triangular ciliated cells, containing a coarsely granular protoplasm ; some of these are provided with a ciliated funnel and project freely into the body-cavity. The funnel widens out at its free end, where there are a large number of large cilia which bend over the surface of the cell, and keep up a constant movement. A canal may be made out which extends into

* Zool. Anzeig., v. (1882) pp. 400–6.
† See this Journal, i. (1881) p. 468.

the base of the funnel and there ends in a certain number of vacuoles; the author has convinced himself that these remarkable structures are an integral part of the animal, but he is not able to make any generalizations with regard to them.

In the highest Siphonophora the mesoderm is represented by the widening out of the lamella, at certain points, into a well-developed gelatinous layer.

While in the lowest, the Calycophorida, an air-sac is absent, it only becomes more complicated as the organization of the Siphonophore becomes higher; in these, however, it is still lined by ectoderm, and never becomes, as Gegenbaur supposed, completely closed. Some of the cells of the ectoderm are of very large size; only one or two cells forming cæcal processes 2 mm. long; the cells themselves may be 1 or $1\frac{1}{2}$ mm. long, and their oval nuclei measure ·13–15 mm., so that they are among the very largest known in animal tissues.

Development of Tubularia cristata. [*] — The development of Tubularian Hydroids has been a subject of some dispute. The latest paper, that of Ciamician, [†] describes an irregular segmentation resulting in an epibolic gastrula. This result, so out of accord with the development of other Hydroids, has been much questioned and denied, and H. W. Conn has accordingly made a careful study of the Tubularian embryo, in the case of *T. cristata*, avoiding the sources of error in Ciamician's observations by removing the egg completely from the medusa and examining it by itself. In the result he finds that the development of *T. cristata* agrees completely with other Hydroids, the segmentation and formation of the germinal layers coinciding completely with Cœlenterates in general. *Tubularia*, which has been considered somewhat of an anomaly in Hydroid development, presents, therefore, no noteworthy difference from the rest of the Hydroids.

American Acalephæ. [‡] —J. W. Fewkes is adding considerably to our knowledge of these forms. In discussing the characters of the Ctenophore *Ocyroë crystallina*, the author points out that, according to the classification of Chun, in which the Ctenophora are divided into the Tentaculata and the Nuda, the form in question would be placed with the non-tentaculate *Beroë*, with which it has few other anatomical likenesses. If Chun's classification is to be followed *Ocyroë* must be regarded as a form connecting his two groups, and indeed it has, as A. Agassiz has pointed out, " structural characters of the Lobatæ, Saccatæ, and Eurystomæ."

After describing *Cassiopeia frondosa*, the author comes to *Linerges mercurius*, which appears to be very abundant in the Gulf off the Florida Keys; one of its most interesting characters appears to be the characters of the "hood" of the prominent otocyst; when this latter is looked at from above it resembles a spherical sac, in the centre of which a single otolith may be seen, seated on a short peduncle; the

* Zool. Anzeig., v. (1882) pp. 483–4.
† Zeitschr. f. wiss. Zool., xxxii.
‡ Bull. Mus. Comp. Zool. Cambridge, ix. pp. 251–310 (10 pls.).

sac is regarded as being the homologue of the hood of other Disco-phora. In development an unequal segmentation is to be observed, and as this segmentation takes place in the water we cannot regard the subumbral pouches as being receptacles for the developing young. During the ephyra stages the cavity of the stomach becomes differ-entiated into an upper and a lower story by the " growth of a con-tinuation of the lower floor of the bell into a partition in this structure."

Stephanomia atlantica is a new species of that genus of the Sipho-nophora which is distinguished by the multiserial arrangement of the swimming bells ; the nectocalyces are much more numerous than in *Agalma* or *Halistemma*, and allow of more varied motion on the part of the animal, and a rotation of the stem is sometimes combined with a direct forward motion. *Agalma papillosum, Agalmopsis fragile, Rhizo-physa gracilis,* and *Athorybia formosa* are new species; in the last we find two different kinds of tentacular knobs hanging from one tentacle.

Halitiara is the name applied to a new genus of Hydroida ; this Tubularian medusa has a tall bell with a small apical projection, four chymiferous tubes without lateral glands, four long tentacles with three small ones between each, and no otocysts. *H. formosa* n. sp. Another new genus is *Halicalyx, H. tenuis ; Aglaura vitrea* n. sp., allied to and perhaps identical with the common *A. hemistoma.*

Three new genera of Hydroids resulted from the explorations of the United States Fishery Commission : *Calycopsis* (*C. typa*) is related to *Turris,* but is distinguished by the presence of sixteen instead of four radial tubes, a point in which it differs from all known Antho-medusæ ; *Chromatonema* (*C. rubrum*) is a form the alliances of which are still somewhat obscure. *Halicreas* (*H. minimum*) has " eight prominent rounded projections covered with tubercles on the bell margin at the extremity of eight radially arranged ribs passing from centre to circumference of the bell. No proboscis. No tentacles." Apparently allied to the Narcomedusæ, it differs from all of them in the presence of the eight radial stripes in the bell, and the eight marginal tubercles. There is a velum which indicates that it is a true Hydroid medusa.

The author discusses the development of the chymiferous tubes in *Mnemiopsis leidyi* and points out the radical differences between it and *Bolina,* the history of which has been related by A. Agassiz.

Sense of Smell in Actiniæ.*—Mr. W. H. Pollock and Dr. G. J. Romanes have found that the common sea-anemones are conscious of the presence of any kind of food (pieces of cockle, mussel, &c.) placed near them. If the food was held within a span's breadth of an indi-vidual anemone the creature opened ; if it was held in the centre of a circle of anemones they gradually opened in succession. They were found to be unable to localize the direction in which the food was lying.

Dr. Romanes considers that the sense which is thus shown to be

* Journ. Linn. Soc. (Zool.) xvi. (1882) pp. 474–6.

possessed by these animals may most properly be called a sense of smell, and they are the lowest animals in which any such sense has hitherto been noticed. It was not found practicable to determine by experiments whether the sense is restricted to any special part of the organism or is diffused over the whole.

Protozoa.

·**Ciliation of the Hypotrichous Infusoria.***—J. van Rees, in a preliminary paper to a larger work on the marine Infusoria, describes in considerable detail the ciliation (more especially) of *Styloplotes grandis* n. sp. A new diagnosis is given of *Euplotes longipes*, whose ciliation is compared with that of the former.

Species of Vorticellæ.—Mr. W. Saville Kent in the third vol. of his 'Manual of Infusoria' gives a plate constituting a very useful key to the numerous species of the genus *Vorticella*, each of the forty-two species being represented in diagrammatic outline at its most typical condition of extension.

Acinetidæ.†—E. Maupas has studied the forms obtained by him in Algiers and at Roscoff in Brittany, and describes at length *Sphœrophrya magna*, *Podophrya limbata*, *Acineta pusilla*, *A. Jolyi*, *A. emaciata*, *A. fœtida*, *Hemophrya thouleti*, and *H. microsoma*. An important observation is recorded as to the ingestion of food by *S. magna*. When an Infusorian is caught a rupture in its cuticle is produced at the point of contact with the tentacle. According to the author the axillary substance of the latter consists of clear homogeneous sarcode continuous with that of the body of the Acinetan, and this passes into the Infusorian, and probably accelerates its death. The tentacle now increases greatly in thickness, due without doubt to the afflux of sarcode from the Acinetan, from which a current is thus established in the direction of its prey, not, however, visible in consequence of the transparency of the sarcode stream. The latter mixes freely with the contents of the victim's body, and loading itself with assimilable substances returns in the inflowing stream, which is so plainly visible by reason of the opaque granular particles held in suspension. This phenomenon is directly comparable with the sarcode circulation in the extended pseudopodia of Foraminifera or cyclosis in plant-cells, though in the former both streams are visible.‡

The author adds a full summary of the general facts which the special studies of the species have, in his opinion, established in regard to the structure and histological constitution of the *Acinetæ*, and some of the controversies which have existed on the subject.

The first question considered is whether any *naked* Acinetidæ exist, destitute of all external covering, with bodies simply composed

* Rees, J. van, 'Zur Kenntniss der Bewimperung der Hypotrichen Infusorien nach Beobachtungen an *Styloplotes grandis* n. sp. und *Euplotes longipes*.' Amsterdam, 1881, 44 pp. and 1 pl.
† Arch. de Zool. Expér. et Gén., ix. (1881) pp. 299–368 (2 pls.).
‡ Cf. for a discussion on the importance of this phenomenon Kent's 'Manual of the Infusoria,' iii. (1882) pp. 803–5.

of a mass of naked sarcode, without differentiation at the periphery into a membrane or other tegumentary layer of any kind. On the one hand, Stein and Fraipont consider all Acinetidæ without exception to be provided with an integument; whilst Cienkowski and Hertwig affirm that they have vainly sought for any integument in *Podophrya fixa*, whose body is naked. After examining the arguments of either side, the author states his own adherence to the view of the latter, what he has himself observed in *Sphærophrya magna*, still further supporting it. The periphery of this species is simply bounded by a thin cortical zone of hyaline sarcode, not distinct from the medullary sarcode, and showing none of the differentiations proper to the true membranes with double outline. The existence of Acinetidæ completely destitute of all covering membrane must, therefore be considered a well-established fact.

With regard to their *integument* the Acinetidæ being unicellular organisms, we must accept as a cell-membrane any peripheral layer with a double outline, which may exist closely applied to the surface of the body, and the author, after a long retrospective discussion of the views hitherto held (by Stein, Claparède and Lachmann, Hertwig, and Fraipont), states his own views. The Hemiophrya and Podophrya are provided with a single tegumentary covering which corresponds morphologically to a cell-membrane. The integument of *Dendrocometes, Dendrosoma, Ophryodendron,* and *Irychophrya* has the same value. The capsule, in which *Acineta* and *Solenophrya* are lodged, cannot, on the contrary, be compared to a cellular membrane, but is only a skeletal structure having no homology with the integument of the other genera. The existence of a second membrane within the shell, and applied to the surface of the body of the *Acinetæ*, has not been definitively shown in any species of this genus, and he is able positively to deny its presence in those which he has studied.

The existence among certain Acinetidæ of two sorts of *tentacles*, one destined for seizing prey, and the other for its suction, is a well-ascertained fact which requires no further support. Although differentiated in their functions, the two kinds have, however, the same morphological value, and are evidently derived from the same primitive organ. Fraipont has given excellent reasons in support of this view, and to these the author further adds the fact that in *Hemiophrya gemmipara* both kinds of tentacles penetrate into the body, whilst in *Hemiophrya microsoma*, the sucking tentacles alone have this internal prolongation. There is here a gradation in the differentiation and specialization of structure, which added to other analogous facts mentioned by Fraipont, shows that these two distinct forms are derived from one primitive form, which, in its structure and its relations with the body, must be similar to that which exists in *Podophrya* and *Sphærophrya*. Fraipont calls this primitive organ a *prehensile sucker*, wishing thus to point out its double function of absorbing and seizing.

Two very different opinions have been held as to the structure of the tentacles. On the one hand Claparède and Lachmann define them as " hollow tubes with contractile walls furnished with a sucker at

their extremity," and Zenker (in describing *Acineta ferrum-equinum*), says " The internal canal of the arms is enveloped in two layers, one internal, voluntarily contractile throughout its whole length and muscular, so to say, in its nature, the other external, inert, membranous, in continuity with the cuticular membrane of the animal." On the other hand, Stein, Hertwig, and Fraipont describe the tentacles as composed of clear homogeneous contents, enclosed in a thin membranous wall. The author thinks that both these opinions are true, and that according to the species, the tentacles may be constituted with the two structures described by these authors. In certain species (*Sphærophrya magna, Acineta fœtida* and *A. emaciata*), the tentacles have a direct dependence on the peripheral zone of the body ; in *Hemiophrya gemmipara*, on the contrary, they are organs become completely independent of the integument, perforating the latter and burying themselves in the substance of the body. Between these two extremes we find, in *Hemiophrya microsoma*, an intermediary arrangement in which the prehensile tentacles are a direct prolongation of the tegument, whilst the sucker tentacles are formed of independent tubes, as in *H. gemmipara*. In very emaciated specimens of *Acineta fœtida*, become very transparent, the author observed a different disposition of the tentacles. The two fascicules were inserted at the extremity of a large tubular prolongation half invaginated in a deep depression of the body, and projecting a little beyond the opening of the shell.

Having examined the structure of the tentacles and their relation to the body, the author turns to the solution of the question to what organs they can be compared in the general morphology of the Protozoa. Are they *sui generis* or can any homologues be found ? Koelliker, Haeckel, and Kent assimilate them purely and simply to the pseudopodia of the Rhizopoda and Radiolaria ; Stein and Claus compare them to pseudopodia, but without affirming any real homology ; whilst Claparède and Lachmann, Hertwig, and Fraipont consider them to be entirely different. Here, again, the author considers that in all three views there is some truth if they are limited to certain species instead of being generalized. There is a great resemblance between the tentacles and pseudopodia, both in regard to their structure and their function, but he would not, nevertheless, consider them as absolutely identical, the consequence of which would be to class the Acinetidæ with the Rhizopoda. They are organs of equal morphological value, between which there does not exist any essential difference of origin and nature and which consequently ought to be considered as homologues in spite of the particular differentiations which have managed to survive in certain types.

The author has little to say of the *nucleus*, the structure and *rôle* of which have been studied with so much skill by Hertwig, that subsequent observers, such as Bütschli and Fraipont, have only confirmed his observations. He adds, however, that the substance of the nucleus is not always as homogeneous as in *Hemiophrya gemmipara*, and that in it may be found a special histological structure, such as is seen in that of *Acineta Jolyi*, containing numerous perfectly spherical vacuoles,

each with a central corpuscle, or in that of *Acineta fœtida*, formed of a sarcodic network with irregular meshes. These two arrangements are also found, the former among ciliated Infusoria, *Climacostomum virens* and *Uroleptus piscis*, the latter in another Acinetan, *Dendrocometes paradoxus*.

As to the *nucleolus*, Stein affirms that no trace of one has ever been found, whilst Koch, Hertwig, and Bütschli do not refer to it. Fraipont alone states that he has found *within* the nucleus of *Ophryodendron belgicum*, *Acineta tuberosa*, and *A. vorticelloides*, one or more much darker corpuscles of nucleolar appearance ; but Koch has studied a species of the first genus and Hertwig *A. tuberosa* without finding any nucleolus, and the observations of Fraipont are too doubtful to be accepted. The author has, however, examined *A. fœtida* and *Podophrya limbata*, and has always found a nucleolus *exterior* to the nucleus, and similar in form and size to the nucleolus of the ciliated Infusoria. The animals were killed with a 1 per cent. solution of acetic acid or by the vapours of a solution of osmic acid of similar strength, then coloured with carmine, and after being washed, cleared with pure glacial acetic acid, for which was finally substituted glycerine, leaving it to penetrate in proportion as the acid evaporated.

Our knowledge of the Acinetidæ is, in M. Maupas' view, much too incomplete to definitely establish their systematic position in the Protozoa. Too much has been made of some of their resemblances to the Ciliata, whilst the considerable and fundamental differences have been neglected. If the author were asked to what group they have the most affinity, he would reply that they have much affinity with the Heliozoa. There is a great resemblance in the disposition, structure, and the mode of action of the pseudopodia of the latter and the tentacles of the Acinetidæ. This resemblance is still more striking when we remember the manner in which *Podophrya Trold*, according to Claparède, devours its prey, the suckers enlarging enormously and swallowing their captives, making them penetrate whole into the body, instead of sucking them slowly as in the other Acinetidæ. This mode of prehension of the food much resembles that of *Actinosphærium Eichhorni*, and gives us one more link between the two kinds of organs. " Are we then to consider the Acinetans as derived from the Heliozoa ? I think that would be going much too fast. . . . Between these two groups of Protozoa there exist, particularly in the phenomena of reproduction, differences too great for it to be possible to admit a direct filiation. Let us be content for the present with having indicated their points of resemblance without wishing to deduce consequences to which perhaps they do not lead."

New Type of Porcellanous Foraminifera.[*] — Mr. H. B. Brady describes from the ' Challenger ' expedition a new genus and species (*Keramosphæra Murrayi*), which illustrates a very distinct and independent type of foraminiferal structure not previously described, though closely related to certain well-known porcellanous forms, and presenting a certain analogy to *Orbitolites*.

[*] Ann. and Mag. Nat. Hist., x. (1882) pp. 242–5 (1 pl.).

The test is free, porcellanous, spherical, formed of concentric layers, each consisting of a large number of chamberlets arranged more or less regularly in single series. Chamberlets of the same layer communicate with each other by short lateral stolons; those of the successive layers by the pores which formed the superficial apertures of the previous layer. Aperture consisting of numerous pores, one at the margin of each chamberlet. Colour white; surface areolated by the outlines of the somewhat convex chamberlets of the peripheral layer. Diameter about $\frac{1}{10}$ inch (2·5 mm.). The specimens were found in material dredged during the 'Challenger' expedition at a depth of 1950 fathoms, in a locality, roughly speaking, about 25° south of the south-western corner of Australia. The material brought up was a nearly white, feathery-looking, diatom-ooze, composed chiefly of Diatomaceæ, Radiolaria, sponge-spicula, and other siliceous organisms. Foraminifera were not very numerous, about seventeen species in all; and the general aspect of the Rhizopod-fauna was distinctly arctic, except that the calcareous forms were as a rule somewhat thin-shelled.

Bacterium rubescens Lank.=Monas Okenii Ehr.* — L. Olivier considers that he has established that the *Bacterium rubescens* of Prof. Lankester† is not a *Bacterium*, but is in reality *Monas Okenii* of Ehrenberg.

The organisms were found by the author in the basins of the Jardin des Plantes at Paris, to which they gave a strong red colour. They were recognized by Prof. Lankester as being *Bacterium rubescens*. They are of a cylindrical form, slightly compressed towards the middle, and slightly swollen at the extremities. The greater axis measures from 0·02 to 0·3 mm., the smaller axis 0·008 mm. The body is colourless, but contains spherical globules of an intense red. These, instead of being disseminated here and there through the protoplasm, are more often arranged in a linear series, following the greater axis. They swim very rapidly, sometimes turning spirally round the greater axis, and progressing in a rectilinear direction. There are two distinct conditions of the organism, the one characterized by the great number of the red globules, the frequent division of the body, and the rapidity of the locomotion; the other by the disappearance of the red globules and the slackening of the movements, and of the tendency to transverse segmentation. Every transition, from the first to the second of these stages, and even from the second to the first, is to be found. If we saw the elongated organisms, still active, but not in the condition of division, in a medium rich in nutritive substances, such, for instance, as broth sufficiently diluted with water, the little organisms will soon be seen to divide ; and the segmentation may even be so frequent, that it sets in before the body of the animalcule has acquired one-third of the length it attains in circumstances where the segmentation is slower. The number of red globules diminishes in proportion to the activity of the organism.

* Bull. Soc. Bot. France, xxviii. (1882) pp. 216–26 (1 pl.).
† Quart. Journ. Micr. Sci., xvi.

This coincidence between the disappearance of the globule and the lessened activity leads to the belief that the globule constitutes a reserve of material for the organism.

To determine the animal or vegetable nature of the organism, the author employed various reagents. By distilled water they were slowly, and by glycerine, alcohol, and acetic acid instantaneously killed, the red colour disappearing slowly with glycerine, but rapidly in the case of the alcohol and the acid. A 1 per cent. solution of iodine is also a violent poison, causing the rapid disappearance of the pigment, and colouring the organism slightly yellow. Chloriodide of zinc acts in the same way, but the colour is a brownish yellow. Iodine and sulphuric acid used simultaneously also give a brown colour if they are not too dilute. Picric acid gives a green colour and carmine red, but if they are used successively (the carmine last), the protoplasm is coloured green and the granulations red, the centre of each remaining clear. The periphery of the body is not differentiated from the central protoplasm. Finally, an alcoholic solution of hæmatoxylin gives no colour.

After the action of these reagents no nucleus could be discovered, whatever was the stage of the life of the microbion, either in the different stages of transverse segmentation or during the increase of the body in length, a fact which deserves attention, as it affords an instance of the division of protoplasm into two individualities without it having been possible to observe any previous differentiation of its constituent parts.

There is also clearly no cellulose ternary vegetable envelope at the periphery of the body, as all the reagents which colour the protoplasm colour the external portion, and *vice versâ*. With fuchsin the colouring is general, as with carmine; it is of an equally intense red in the different regions, whether internal or peripheral. In the same way with Paris violet, it is impossible to distinguish the external membrane from the subjacent protoplasm. This membrane is, therefore, simply a protoplasmic envelope, like that of the Infusoria, and cannot be compared to the cellular membrane of the Bacteria.

The use of reagents leads us, moreover, to recognize the existence of organs very different from those which have been described among the Bacteria. In treating the organisms with a concentrated solution of Paris violet, we see at one of the two extremities, seldom at both, a filament, about 2 or $2\frac{1}{2}$ times as long as the body. It is very slender, and does not resemble the caudal prolongations which Koch has described as cilia among the *Bacilli*. It takes the same colour as the rest of the body. The existence and position of this filament leave no room for doubt, in the author's opinion, that *Bacterium rubescens* is *Monas Okenii*. Ehrenberg and Cohn's descriptions of the latter also agree in all points with that of *B. rubescens*. The filaments of *Monas* differ also from those of the Bacteria by their greater length and by the fact that they are cylindrical from their base to the free extremity.

Van Tieghem considers the caudal filaments of the Bacteria to be prolongations of the cellular membrane, and not protoplasmic cilia

endowed with spontaneous movement.   M. Olivier, therefore, thought it interesting to examine whether the same was the case with *Monas Okenii*, or whether, on the contrary, their long filaments are formed in a different manner.

In a large graduated vessel 30 c.cm. of water was collected so rich in *Monas Okenii* as to be coloured red by them.   One c.cm. of 1 per cent. osmic acid was added, and five minutes afterwards the vessel filled with distilled water, in order to weaken the destructive action of the acid.   The next day all had fallen to the bottom, and by simple decantation an immense number could be collected in a very small bulk.   Observed under the Microscope they presented different degrees of division.   Those in which the segmentation was the deepest appeared to be entirely separated into two distinct masses.   This is the case during life also.   We then see two masses of the same shape opposed end to end, but leaving between them a transverse furrow which is quite colourless.   When the *Monad* moves, these two masses move simultaneously. showing that they are united by a real though invisible tie.   But if, when killed by osmic acid, they are subsequently treated with Paris violet, that which before had the appearance of a hyaline furrow—a complete interval between the two segments of the body—immediately becomes coloured in the same way as the best characterized filaments.   This portion appears to be in continuity with the protoplasm, no reagent distinguishing one part from the other.   As the two segments of the body become further separated, this connection grows thinner and finally breaks.   Although he did not succeed in following all the phases of this phenomenon in their successive order, the author " attributes to the connection which unites the two segments of the *Monad* the same nature as to the long and slender filament previously described.   Like this filament the connection is invisible without special preparation, but is easily recognized when coloured with Paris violet."

Cohn has remarked that the *Monas* in act of transverse division have a cilium at both extremities.   But, in fact, one extremity is much more often destitute of any.   The formation of a cilium at the free extremity of a *Monad* was never observed.   The filaments, always cylindrical, are evidently flexible, for they present every imaginable appearance and position when coloured with Paris violet after being killed by osmic acid.   Some experiments on dead organisms lead to the conclusion that the filaments are contractile, for on putting them into distilled water they in a few days disappeared; and this disappearance can only be explained by destruction or contraction. When the animals are fixed by osmic acid, left for some days in distilled water, and coloured by means of Paris violet, the filaments become visible; and it therefore seems that the osmic acid, by instantly killing them, prevents a contraction which would otherwise take place.

All these facts show that *Monas Okenii* does not resemble any species of *Bacterium*.   Their organization, on the contrary, refers them to the nudo-flagellate Infusoria, as for example, *Spumella*.   Like a great number of Infusoria (especially the *Euglenæ*), they seek the

light. The glass vessels in which they were kept were red at the side turned towards the light, whilst the opposite side remained colourless. If the vessel was blackened so that light could only penetrate through a small orifice, the *Monas* abandoned the dark regions and concentrated themselves in the light. This is not the only red organism that shows this attraction to light; and this circumstance has led to its being confounded with an Alga which has the same colour, and is deposited in the form of large pellicles on the walls of vessels exposed to daylight. *Claythrocystis roseo-persicina* is thus often found associated with *Monas Okenii.*

Oviform Psorospermiæ or Coccidia.*—A. Schneider gives the following as a provisional classification of the Psorospermiæ :—

Tribe I. The whole of the contents of the cyst are converted into a single spore. MONOSPOREÆ.

    a. Spore enclosing a definite number of corpuscles. Oligozoids. Corpuscles four in number. *Orthospora.*

    b. Spore enclosing an indefinite number of corpuscles. Polyzoids. *Eimeria.*

Tribe II. Contents of cyst becoming converted into a constant and definite number of spores. OLIGOSPOREÆ.

    A. Only two spores. (Disporeæ.)

    a. Corpuscles of the spores in definite number. *Cyclospora.*

    b. Corpuscles of the spores in indefinite number. *Isospora.*

    B. Four spores. (Tetrasporeæ.) Corpuscle, one. *Coccidium.*

Tribe III. Contents of cyst becoming converted into a great number of spores. POLYSPOREÆ. *Klossia, Benedenia.*

The author then describes three new genera (*Orthospora, Cyclospora,* and *Isospora*), with three new species, and two other new species of previously known genera.

BOTANY.

A. GENERAL, including Embryology and Histology of the Phanerogamia.

Development of the Embryo and Embryo-sac.†—M. Treub states that *Peristylus grandis* furnishes an excellent demonstration of the fact previously recorded by him ‡ that in the Orchideæ the suspensor performs the function of a nutritive organ for the embryo. Some time after fertilization the embryo-sac is found to contain a small suspensor composed of a row of two or three cells. The upper portion of this soon grows rapidly, and finally protrudes beyond the exostome, putting out digitate much-branched protuberances, which creep over the funiculi and placentæ, robbing them of their non-nitrogenous contents for the benefit of the embryo ; the cells of the

    † Ann. du Jardin Bot. de Buitenzorg, iii. (1882) pp. 76–87 (3 pls.). See Bot. Centralbl., x. (1882) p. 356.
    ‡ See this Journal, iii. (1880) p. 474.

suspensor often temporarily contain starch. Immediately after receiving this supply of food-materials, the embryo, which had hitherto undergone very little change, alters in form and increases greatly in size, assuming the ordinary globular form of the embryo of Orchideæ. In *Peristylus* the embryo appears to receive the whole of its nutriment in this way, while in European orchids a portion is derived from the ovule itself.

Avicennia officinalis presents this peculiarity: that the two cells formed by division of the sister-cells of the embryo-sac are not, as is elsewhere the case, resorbed or compressed. A short time after fertilization the embryo-sac contains endosperm-cells which surround the embryo, and one large cell reaching to its apex, which the author calls the *cotyloid cell.* Subsequently the endosperm gradually emerges from the embryo-sac; the embryo undergoes in the meantime further development, and after a time is covered only on one side by a thin layer of endosperm. In this layer a cleft is formed through which the cotyledons project, while the lower end of the embryo remains in the endosperm. The upper part of the cotyloid cell, together with the endosperm, projects out of the micropyle; while its lower part, still enclosed in the ovule, puts out protuberances on all sides into its tissue and into the placenta, which, after a time, it completely permeates like a mycelium. The cotyloid cell undoubtedly performs the same function as the suspensor in orchids, viz. that of a nutritive organ, carrying to the embryo, through the endosperm, the nutritive substances contained in the ovule and in the placenta.

Embryogeny of the Leguminosæ.[*]—The following are the main results of an extensive series of observations made by L. Guignard on the development of the embryo and embryo-sac of a number of plants, mostly belonging to the Leguminosæ. His general conclusions do not confirm the theory of some writers that the nucellus of the embryo-sac is the homologue of a pollen-grain or spore.

The axile hypodermal cell of the nucellus divides horizontally into two cells of variable size, the apical and the subapical cells. The apical cell either remains undivided or gives rise to a tissue of varying thickness, the "calotte." This tissue is especially developed in the Mimoseæ and Cæsalpinieæ at the period of impregnation; in the latter group it remains for a time after impregnation. The subapical cell (primordial mother-cell of Warming) may either remain undivided, and develope directly into the embryo-sac (*Medicago, Melilotus*), or it divides into a variable number of superposed cells, the lowermost of which (the true mother-cell) displaces the others, and alone developes into the embryo-sac. Cases are described in which the number of these cells is two, three, and four respectively. The order of formation of the cell-walls is usually basipetal; they may be thicker or not than the neighbouring cell-wall. With possibly the single exception of *Acacia albida*, the embryo-sac is invariably the product of the lowermost cell, never of the fusion of two cells.

---

[*] Ann. Sci. Nat. (Bot.) xii. (1881–2) pp. 1–166 (8 pls.). Cf. this Journal, iii. (1880) p. 473; i. (1881) pp. 69, 260, 620; *ante*, p. 64.

It would appear, however, from observations made by other writers in the case of other plants (especially by M. Mellink on *Agraphis patula*) that there is a certain equivalence in the cells of the axile row, and that one or other of them may develope into the embryo-sac, but only one. Nevertheless, in some species the presence of two nuclei in the penultimate cell is nearly constant. The occurrence, or otherwise, of divisions in the subapical cell appears to depend on the greater or less rapidity of the development of the embryo-sac. This tendency to division is even continued in the embryo-sac itself, but is arrested and reduced to the remarkable division of its primary nucleus into two parts, which separate to the two extremities of the sac. The formation out of this primary nucleus of eight distinct nuclei takes place in the way described by Strasburger; but their exact position varies according to the form of the cavity. The upper nucleus divides into the oosphere, the two synergidæ, and a polar nucleus; the lower one into the three antipodals and a polar nucleus. The synergidæ are more or less closely attached to the summit of the embryo-sac; in the Mimoseæ they often attain a considerable length. The oosphere is inserted laterally, and descends below the synergidæ; its appearance varies considerably at the time of impregnation. The three antipodals are attached to the base of the sac, and are generally clothed with a thin membrane. In *Phaseolus* this is of considerable thickness; but it subsequently disappears, and the antipodals themselves have entirely vanished at the time of impregnation. In the Ranunculaceæ and Papaveraceæ, on the other hand, they survive this period. They are most developed in the Mimoseæ and Cæsalpinieæ. The fusion of the two polar nuclei takes place at different parts of the embryo-sac. It is completed before fertilization, except perhaps in the Vicieæ.

The author regards all the cells formed in the embryo-sac of Angiosperms as representing endosperm-cells analogous to those formed in the embryo-sac of Gymnosperms. The oosphere forms by itself a greatly reduced archegonium; the synergidæ are endosperm-cells adapted for a special function. The endosperm formed after fertilization by division of the secondary nucleus is the recommencement of an interrupted development.

With regard to the formation of the embryo, the first step is invariably the appearance of a transverse wall in the fertilized cell; but from this point great diversities exist, the differentiation of the subsequent product into embryo properly so called and suspensor not being constant. The entire absence of a suspensor had been noticed by Schacht, Treub, and others in a few isolated genera or species, chiefly monocotyledonous. Guignard now establishes that it occurs throughout the Mimoseæ and in some Hedysareæ.

When there is a distinct suspensor, it is differentiated at very different periods of development, according to the following six types:—

1. The suspensor may be rudimentary, and never composed of more than three or four superposed cells (*Soja, Amphicarpœa, Trifolium*).

2. It may be composed of two pairs of cells placed crosswise, the

uppermost attaining a considerable length, while the lowermost assumes a spherical form, both of these being remarkable for the constant plurality of nuclei (Vicieæ, with the exception of *Cicer arietinum*).

3. It may be formed of a filament of cells of variable number (*Ononis*).

4. It may consist of a larger or smaller number of pairs of cells, either superposed or in the same vertical plane (*Lupinus*), or in regular alternation (*Cicer arietinum*).

5. It may be composed of a greatly elongated cellular body, the cells of which are either (1) quite distinct from the embryo (*Medicago, Trigonella*, &c.), or (2) not completely distinct (*Galega*), or (3) much confounded with it (*Phaseolus*, &c.).

6. The cellular body may be an ovoid or rounded mass, which may differ as to the size, form, number, arrangement, and contents of the cells, and as to their relation to the embryo (*Cercis, Anthyllis, Cytisus*, &c.).

In the same genus of Leguminosæ the type remains as a rule constant, but differs within the tribe. In the Fumariaceæ we find, on the contrary, *Corydalis ochroleuca* with a much-developed suspensor, while *C. cava* is entirely destitute of one. In the order Leguminosæ we find every type that occurs in all the other natural orders.

With regard to the formation of the embryo itself, after the primary transverse segmentation which immediately follows fecundation, sometimes the lower cell is itself the mother-cell of the embryo, sometimes the mother-cell is not differentiated till after further divisions in the suspensor; the first case occurring in *Lotus, Tetragonobolus, Trifolium, Medicago, Anthyllis, Phaseolus*, &c., the second in *Galega* and the Vicieæ. The first division in the embryo is not, as has often been stated, invariably longitudinal; in the Vicieæ it is transverse.

The epidermis becomes differentiated on the surface of the embryo before the appearance of the cotyledons. In embryos without suspensor, as those of the Acacieæ, the internal tissues are most strongly differentiated; in the Vicieæ, on the other hand, the cotyledons are already considerably developed while the axis is still very short and shows no internal differentiation. The size of the axis, as compared to that of the cotyledons, varies greatly. In most of the Mimoseæ it is very short, and manifests, long before it has attained any considerable length, the lobes of its first compound leaves. In this tribe also the synergidæ sometimes develope into embryos, indicating that they may probably partake of the nature of oospheres.

The endosperm exists in the embryo-sac in two different states, either of free nuclei on the cell-wall, or of a parenchymatous temporary or permanent tissue; the second always succeeding the first, except in the true Vicieæ. The mode of multiplication of the endosperm-cells presents a close analogy to that of the suspensor; fragmentation is a phenomenon associated with age. The first cell-walls always make their appearance at the summit of the embryo-sac, except in *Lupinus*. The free nuclei always divide simultaneously, as also do those of the

cells. Whether the endosperm is temporary or permanent, its cell-walls are always very thin up to the time when the embryo attains its full dimensions; then either its resorption commences, or it becomes gradually transformed into a solid permanent tissue. The presence of endosperm in the mature seed must be regarded as a sign of inferior organization. Its presence is not, however, always constant in the same genus, and it cannot be considered a character of primary importance in classification.

The period of first formation of the endosperm varies considerably. In the Mimoseæ, Cæsalpinieæ, and those Papilionaceæ where there is no suspensor, or only a rudimentary one, it begins to develope when the embryo consists of only about a dozen cells; while in those cases where the suspensor is more developed it originates considerably later. The suspensor, having very often a development in inverse proportion to that of the endosperm, or being formed considerably earlier, has undoubtedly in many cases, like the latter, a function of supplying the embryo with nutrition, though in other cases it may serve no other purpose than that of fixing it.

The author considers that these embryological facts do not yet enable us to assign to the Leguminosæ their genetic position in the series of vegetable organisms.

Development of the Ovule of Primula.*—According to F. Pax, the ovules of *Primula elatior* and *officinalis* are formed in basipetal succession, but leaving the apex of the placenta and the part next the base of the ovary free. Between the ovules are formed, also basipetally, and after the first appearance of the integuments, emergences of large-celled parenchyma, varying in size with the species, as also does the number of ovules, which is usually larger in the short-styled than in the long-styled form. The ovules are arranged spirally.

In *P. Auricula* and *elatior* the initial cell of the ovule lies beneath the dermatogen, and first divides by an anticlinal wall into two cells, which then divide periclinally, and one or both of the outer segments again anticlinally. The number of rows of cells produced by the periclinal divisions is increased by anticlinal divisions, and the dermatogen-cells are also found to divide anticlinally. When the rudimentary ovule begins to be elevated as a protuberance, periclinal walls are also formed on the apical surface of the protuberance in the first, less often in the second layer beneath the dermatogen and anticlinal walls on its lateral faces in the first layer beneath the dermatogen. No differentiation can yet be detected into periblem and plerome; and the term *endoblem* is applied by the author to the tissue beneath the dermatogen. The endoblem finally forms a small-celled parenchymatous tissue.

The formation of the nucellus is preceded by a radial elongation of the cells of the outermost layer of endoblem, and the ovular protuberance now becomes cylindrical, with a nearly rectangular longitu-

* Pax, F., ' Beitrag zur Kenntniss des Ovulums von *Primula elatior* Jacq. u. *officinalis* Jacq.' 41 pp., Breslau, 1882. See Bot. Centralbl., x. (1882) p. 316.

dinal section. The nucellus is formed only in the lateral, not in the
terminal corners.   The two integuments are formed at the same time
on one side only around and not out of it, appearing first at the apical
edge of the longitudinal section, and growing also more rapidly here
than at the parts nearest to the base of the ovary.   The inner integu-
ment is clearly formed before the outer one.   Both are developed out
of the dermatogen, while in other genera it is only the inner one that
has this origin.

In the formation of the integuments an elongation of two cells in
the case of the outer, of three in the case of the inner integument
takes place on the dorsal side, their cells being separated from one
another by a single cell.   The elongation takes place in two slightly
different directions.   The outer integument is then formed on the
dorsal side by the growth of the apical edge of the two cells, on the
ventral side by periclinal and anticlinal divisions of originally at most
five cells.   The inner integument is formed on both sides out of three
cells, the central one of which usually divides periclinally, the two
outer ones by oblique walls.

The thickening of the outer integument takes place by divisions
parallel to the longitudinal axis in those cells which form at the time
its innermost layer; the inner integument is formed also in a similar
way, and becomes considerably thicker than the outer one.   The
cells of the innermost layer of the inner integument subsequently
elongate in a direction vertical to the longitudinal axis.   Special
divisions take place in certain cells on the ventral side in connection
with the curvature of the embryo-sac.   The ovule of *Primula* is not
strictly anatropous, but somewhat between the anatropous and
campylotropous form.

The origin of the formation of the nucellus consists in three hypo-
dermal cells of the outermost layer of endoblem raising up the four or
five dermatogen cells which lie above them, and giving rise to anticlinal
divisions.   The centre one of these three cells increases much more
rapidly, forcing aside the other ones, which are completely resorbed in
the epidermis.   In the mother-cell of the embryo-sac arise two and sub-
sequently two more transverse walls of considerable thickness and great
refrangibility.   The lowermost of the four daughter-cells compresses
the three others which lie above it, until they finally constitute only a
strongly refrangible cap upon the mature embryo-sac.   The embryo-
sac is fusiform and somewhat crescent-shaped; it contains two
synergidæ, an ovum-cell or oosphere, a small "vegetative" nucleus,
and three antipodals.

The funiculus is formed out of the original ovular protuberance;
its endoblem is differentiated into periblem and plerome.   The latter
developes into a vascular bundle without xylem, composed only of
cambiform, which ends directly at the embryo-sac.   The periblem is
at first composed of a single layer of elongated cells, later of two
layers, and finally of large cells destitute of protoplasm.

Homology of the Ovule.*—L. Celakovsky gives a very minute
description of a case of phyllody of the ovules of the columbine;

* Bot. Centralbl., x. (1882) pp. 331–42 ; 372–82 (1 pl.).

discusses at great length the various theories as to the homology of
the ovule and of its parts; and finally adduces arguments in favour
of his previously published view that the ovule is homologous to a
pinna or section of a leaf (foliolum). The ordinary position of the
nucellus in the ovule is at first terminal; and it sometimes also
occupies this position in monstrosities, especially when the ovular
leaflet does not assume a distinctly foliar character. But when
phyllody is strongly manifested, it is seen that the nucellus is not
the true apex of the foliar leaflet, having a superficial lateral position.
The morphological value of the nucellus is not affected by the
question whether it originally occupies or only subsequently assumes
a lateral position.

Phytoblasts and their Pseudopodia.*—According to Prof. H.
Baillon every vegetable or vegetable organism commences its existence
as a phytoblast, the life of which may go through distinct periods,
and which may have various degrees of complexity of structure. The
phytoblast is of an albuminoid nature, like the lowest animals; and
its reactions are proteid. Like truly animal substances, it is attacked
by ammonia and by other special reagents; and behaves in every
respect like animal sarcode. With its movements are associated
pseudopodia, produced at the expense of its substance, usually internal,
less often external. The movement of these pseudopodia is ordinarily
slow, but sometimes more rapid, acting as arms to extend the
organism to any neighbouring locality where the conditions may be
especially favourable for its nutrition.

During the growth of the pseudopodia cavities are formed inside
it through which circulate a variety of nutrient fluids, one of these
being the chlorophyll-pigment, though many phytoblasts are entirely
destitute of it. Another frequent product of the phytoblast is the
phytocyst, an external envelope of cellulose, mixed with a certain
proportion of the superficial proteid substance; but which must be
regarded only as a kind of carapace belonging to the moneroid
structure which represents the phytoblast.

A favourable object for observing the structure and movements of
these pseudopodia is the hairs at the base of the stamens of
Ficoideæ; within which are seen, in favourable conditions, proto-
plasmic structures with a rapid oscillating motion resembling that
of vibratile cilia. These pseudopodia coalesce when they meet, and
the internal microsomes move rapidly from one to another. The
author compares this movement to that of plasmodia, and regards
it as forming an argument in favour of the animal nature of these
phytoblasts or phytozoaires.

Formation of Pollen-tubes.†—J.B. Schnetzler places pollen-grains
of *Narcissus poeticus* in the mucilage from the stem of the plant.
After about two hours, pollen-tubes begin to be formed, in which, at
a temperature of 13° C., currents of protoplasm are very evident. The
tubes thus formed vary greatly in form and dimension, while those

* Bull. Soc. Linn. de Paris, 1882, pp. 297–8 and 313–4.
† Bot. Centralbl., xi. (1882) pp. 104–5.

formed in the conducting-tissue of the stigma are moderately uniform. Pollen-grains of *Leucojum æstivum* immersed in the same way at 7 A.M. began to put out their tubes at 10.30; about 11.30 the tubes were twice as long as the grains; about 12.0 three times as long, and at 2 P.M. ten times as long as the grains; increasing in length about 0·1 mm. per hour. If the mucilage is too watery, the grains are liable to burst. Tinting with carmine-ammonia exhibits the development of the pollen-tubes very well when the mucilage in which they are immersed is sufficiently fresh.

Cause of the Movement of Pollen-tubes.*—The penetration of pollen-tubes into the conducting tissue of the style is attributed by Sachs to unequal growth of the two sides; A. Tomaschek, on the contrary, considers it to be due to hydrotropism. When masses of pollen of *Colchicum autumnale* are placed in a hollow plum from which the stone has been removed, the pollen-tubes from the uppermost grains rise erect, while those which lie at the side incline downwards. Pollen-grains made to germinate in the open air display curvatures and even spiral windings, closely analogous to those of tendrils, which can scarcely be assigned to any other cause than revolving nutation.

Apical Growth of the Roots of Phanerogams.†—S. Schwendener gives the following summary of results of his own and of previous investigators on this point:—

1. Most dicotyledons have a formative tissue over the apex of the root, the innermost layer of which is the young epidermis, the remaining layers belong to the root-cap. The originally simple row of cells of which the epidermis is composed splits into two; the inner, and sometimes the outer one of these again divide. In a small number of dicotyledons layers of cells split off from the epidermis outwards, constituting the root-cap; the root-cap and the root itself having in these cases a common histogen. The formation of the root-cap is shared by the epidermis, which covers the apex of the root either in an undivided or in a split condition, and by the entire cortex or its outermost portion only. Monocotyledons have distinct histogens for the root-cap and the root itself; the epidermis is not in genetic connection with the root-cap; but there is a common primary meristem for both. Dicotyledons and monocotyledons present therefore this difference; that in the former there is a genetic connection between the root-cap and epidermis, but not in the latter.

2. The author confirms the statement of Eriksson that in dicotyledons the root-cap and epidermis proceed from a common histogen, the "dermacalyptrogen"; although differentiated dermatogen cells take part in the formation of the cap.

3. There is no distinct histogen, as Hanstein asserts, for the vascular cylinder or plerome.

4. As respects the number of apical cells, *Eleocharis palustris* has only one ; while the Marattiaceæ have four. Phanerogams most often have several, not unfrequently four. In not a few cases, and especially among conifers and in some Leguminosæ, the line of growth takes a peculiar course. At the apex is a column, the rows of cells which constitute it running parallel to one another and to the axis. This structure is regarded as indicating a transverse meristem composed of equivalent cells.

5. When distinct histogens occur in the apex, the walls which separate them are as thin as those of the histogen itself. Even roots, therefore, possess a special meristem from which branches proceed in two directions having no genetic connection with one another.

Pitchers of Dischidia Rafflesiana.*—M. Treub describes the pitchers of this epiphytal liane, belonging to the Asclepiadeæ, which is rarely seen in Europe. The pitchers are seated on short axillary branches in pairs or opposite to very rudimentary leaves, and are themselves metamorphosed leaves, exactly resembling the ordinary leaves in their earlier stages. In contrast to *Sarracenia* and *Nepenthes*, the outer side of the pitcher corresponds to the upper side of the normal leaves. The whole of the plant with the exception of the stomata, is covered with a close coating of wax, which extends even to the inside of the pitchers, and seems to preclude the possibility of these being organs of nutrition. They contain water, due apparently partly to rain, partly to transpiration. The only animals found in them were ants, which were always alive. Many of the pitchers were penetrated by the abundant adventitious roots ; and the only function which could be suggested for them was the accumulation of water, which is conveyed to the plant through these roots.

Influence of Light and Air on the Anatomical Structure of Plants.†—J. Vesque and C. Viet give the following as the main results of experiments on this subject made partly in the laboratory, partly in the open air :—

The combined action of light and of air more or less dry (i. e. of ventilation) is to accelerate the amount of transpiration, and hence (1) to increase the total thickness of the foliage ; (2) to promote the development of palisade-parenchyma, either by the increase in the number of layers of cells of which it is composed, or by increasing the length of the cells themselves ; (3) to promote an increased development of hairs, both in number and in length.

The authors consider that these effects are produced not by one only of the agents, but by the two combined.

Respiration of Plants.‡—E. Godlewski has made a careful series of experiments on the relations between the gases inhaled and exhaled

* Ann. Jard. Bot. Buitenzorg, iii. (1882) pp. 13–37 (3 pls.). See Bot. Centralbl., xi. (1882) p. 57.

† Ann. Sci. Nat. (Bot.) xii. (1882) pp. 167–76.

‡ Denkwürd. Krak. Akad. Wiss., vii. (1881). See Bot. Centralbl., x. (1882) p. 308.

by plants, chiefly by germinating, starchy, and oily seeds, ripening fruits of *Ricinus communis* and *Papaver somniferum*, and flower-buds of the last species. The following are some of the more important results :—

1. In the germination of both oily and starchy seeds, during the period of swelling, the volume of the exhaled carbonic gas is very nearly the same as that of the inhaled oxygen.

2. When access of oxygen is hindered, as when the swelling takes place under water, intramolecular respiration comes into play ; and this may even continue after the seeds are exposed to the direct influence of the air.

3. When, in oily seeds, the roots begin to grow, the quantity of inhaled oxygen begins to show an excess over that of the exhaled carbonic acid. At the time when growth and respiration are most active, about 55–65 parts of carbonic acid are exhaled for 100 parts of oxygen inhaled.

4. The transformation of oil into starch is probably effected by each molecule of oil splitting up into three molecules of starch, together with carbonic acid, water, and other undetermined substances.

5. In the later periods of the germination of oleaginous seeds, not only the oil but also the carbohydrates formed from it, are used up in respiration ; in consequence of which the volumes of oxygen inhaled and of carbonic acid exhaled become eventually equal.

6. In the germination of starchy seeds the volumes of the two gases remain constantly nearly the same, varying somewhat with different species.

7. In the case of expanding buds (of *Papaver somniferum*) the volumes of the two gases are the same.

8. In the case of ripening fruits containing oily seeds, a considerably greater quantity of carbonic acid is exhaled than that of the oxygen inhaled, a process of reduction taking place by which starch is changed into oil.

9. Changes in the pressure of the oxygen cause corresponding changes in the energy of respiration.

10. But even when the energy of respiration is affected in this way, no alteration takes place in the relative quantity of oxygen inhaled and of carbonic acid exhaled. The relative proportion is affected only when the pressure of oxygen is so reduced that the amount of this gas inhaled is considerably diminished, giving rise to intramolecular respiration.

11. Intramolecular is no ingredient in normal respiration, which is the result of the direct action of atmospheric oxygen on living molecules of protoplasm ; the former taking place only when normal respiration is hindered by a deficient supply of oxygen.

12. Under the ordinary conditions of normal respiration, intramolecular respiration takes place only when a process of reduction is going on at the same time in the plant, as when carbohydrates are being transformed into oil.

Oxalate of Lime in Plants.[*]—Dr. A. Poli publishes a full account of what is known respecting the occurrence of crystals of calcium oxalate in plants, including a complete list of those species in which they have been found, and a chapter on their physiological value.

Dr. Poli's own observations relate to species from a great number of natural orders, but chiefly from Labiatæ. The presence of calcium oxalate is, he states, no characteristic feature of this class, several genera being altogether deficient in it. When present, it occurs in the greatest abundance in the rachis of the inflorescence. In some species of *Salvia* the crystals appear to be suspended in the cell-contents of the pith and cortical parenchyma, to be endowed with Brownian movement, and to be accompanied by grains of chlorophyll or starch.

The clusters of crystals which occur in the extrafloral nectaries of *Ricinus* are first formed in the nectaries at the base of the cotyledons, around the vascular bundles. The young seedling has no crystals of calcium oxalate within its tissue until it has attained a height of nearly 0·1 m. and its cotyledons are fully developed. There are no crystals in the male flowers of *Ricinus*.

Insects and the Cross-fertilization of Flowers.[†]—Doubts have been raised by M. Heckel and others, as to the *rôle* of insects in the cross-fertilization of flowers; based especially on their supposed absence, or at least, their great rarity on the flowery summits of high mountains. The results of four years' observations at Grenoble, by C. Musset, at all altitudes from 200 m. to 3000 m., and amidst one of the richest herbaceous floras in the world, are instructive. He finds (1) that all orders of insects have representatives up to 2300 m.; (2) that beyond 2300 m. Lepidoptera, Diptera, and certain Hymenoptera preponderate in number; (3) that the number of genera, species, and individuals of nectar-loving insects is proportional to that of the flowers, and is sometimes incalculable; (4) that the hours of sleep and waking of flowers, and those of insects, are synchronous; (5) that the apparent number of nectar-loving insects is proportional to the number of their favourite flowers, and the state of the atmosphere and sky. M. Musset concludes that, as flowers and insects are never simultaneously wanting, the objection referred to against cross-fertilization is not well founded.

B. CRYPTOGAMIA.

Muscineæ.

Classification of Sphagnaceæ.[‡]—G. Limpricht explains more in detail the use of the character derived from the relative position of the chlorophyllaceous and the hyaline cells for the classification of species of *Sphagnum*.

* Poli, A., 'I cristalli di ossalato calcico nelle plante' (2 pls.), Rome, 1882. See Bot. Centralbl., x. (1882) p. 311. See also this Journal, *ante*, p. 597.
† Comptes Rendus, xcv. (1882).
‡ Bot. Centralbl., x. (1882) pp. 214–22. See this Journal, *ante*, p. 79.

The chlorophyllaceous cells of the leaves of the branches are compressed between the hyaline cells in one series on the inner, in the other series on the outer side of the leaf, forming, on transverse section, an isosceles triangle, with the free outer wall as its base. In the hyaline cells that wall is in consequence more convex which is more or less in contact with the adjoining hyaline cell at the apex of the triangle, although there is never any actual mutual coalescence. In the same species the prismatic form of the chlorophyllaceous cells may be replaced by a triangular, oval, or even a trapezoid form. In this mode of arrangement two groups may be distinguished :—

1. The chlorophyllaceous cells are compressed between the hyaline cells on the outer side of the leaf; the hyaline cells being therefore more convex on the inner side of the leaf :—*S. recurvum*, P. B., and var. *speciosum* Russ. (*S. spectabile* Sch.) ; *Lindbergii* Sch. ; *molluscum* Bruch ; *cuspidatum* Ehrh.

2. The chlorophyllaceous cells are compressed between the hyaline cells on the inner side of the leaf; the hyaline cells being therefore more convex on the outer side of the leaf :—*S. acutifolium* Ehrh. ; *rubellum* Wils. ; *Girgensohnii* Russ. ; *fimbriatum* Wils. ; *molle* Sull. ; *Austinii* Sull. ; *papillosum* and *cymbifolium* Ehrh., with its sub-forms *S. subbicolor* Hampe, and *glaucum* v. Klinggr.

3. In the remaining species of *Sphagnum*, the chlorophyllaceous cells of the leaves of the branches lie exactly in the middle between the hyaline cells ; either (1) free on both sides, when they are fusiform or disk-shaped in transverse section, and the hyaline cells equally convex on both sides :—*S. subsecundum*, N. v. E. ; *laricinum* Spr., and *contortum* Sch. ; or (2) the very small chlorophyllaceous cells are elliptical in transverse section, and are equally enclosed on all sides by the hyaline cells, which mutually coalesce :—*S. Wulfianum* Girg. ; *Angströmii* Hartm. ; *rigidum* Sch. ; and *medium*. The *squamosum* group presents some considerable deviations from this structure.

Fungi.

Leucogaster, a New Genus of Hymenogastreæ.[*] — In beech-woods in Hesse-Nassau, R. Hesse found a number of fungi belonging to the Hymenogastreæ, a group of Gasteromycetes which comprises the genera *Hymenogaster*, *Rhizopogon*, *Hysterangium*, *Hydnangium*, *Gautieria*, *Octaviania*, and *Melanogaster*. Among them he observed a hitherto unknown form, which he describes under the name *Leucogaster liosporus*, and regards as the type of a new genus which must be placed between *Melanogaster* and *Octaviania*. It resembles *Melanogaster* in the chambers of the gleba being filled with jelly in consequence of the swelling of the basidia ; *Octaviania* and *Hydnangium* in the form of the spores ; but differs from all the other Hymenogastreæ in the structure of the membrane of the spores.

The mycelium is not very massive, and consists of thin, at first colourless, septated, branched hyphæ with very thick walls and occa-

sional swellings. The fructification varies greatly in form and in size from that of a pea to a pigeon's egg. The peridium of the mature fructification is from 1·5 to 2·5 mm. thick, smooth, and composed of densely packed yellowish hyphæ. The white shining chambered gleba resembles in structure that of *Melanogaster* and *Hysterangium.* The trama is readily distinguished from the hymenial hyphæ, and is composed of a mass of extremely thin shining filaments, of which the hymenial filaments are elongated unseptated branches. The chambers of the gleba are usually polygonal, and are filled, as in *Melanogaster,* with jelly resulting from the swelling of those basidia which have already produced spores. The ripe spores are yellow, and about 0·02 mm. in diam. They are produced in the ordinary way in fours on the basidia, but without sterigmata. The membrane eventually separates into two layers, an exospore and an endospore; the exospore finally deliquesces into jelly; so that the ripe spore is at length surrounded with a smooth gelatinous transparent envelope, investing it like a sac. The spores contain a dense fine-grained protoplasm, with small drops of oil.

Parasites of the Human Ear.*—Loewenberg states that otomykosis frequently results from the introduction into the ear of the mycelium of fungi through the medium of ordinary oily substances such as olive-oil, oil of almonds, balsam, pomade, &c.; and he recommends as a substitute for these glycerine, which is not liable to the same objection. Disease is also caused by the occurrence of mycelial filaments in liquid medicinal applications, such as tannin, alum, zinc-vitriol, &c. The most extreme care must consequently be taken as to the purity of fluids for dropping into the ear, especially where the drum is perforated.

He also adduces a case of ophthalmomykosis apparently caused by the presence of mycelial filaments in solutions of atropine and chlorine. The use of alcoholic in preference to aqueous solutions is recommended wherever practicable; where the latter are indispensable, they should be boiled, or kept in so concentrated a state that the mycelia or spores of fungi cannot retain in them their power of growth, and diluted with freshly boiled water immediately before using.

Chromogenous Schizomycete on Cooked Meat.†—In some experiments carried out by J. B. Schnetzler, pieces of fresh boiled beef, tendons, bones, and fat, exposed to the air but protected from light, became completely covered with a coating of a beautiful fuchsin-red colour. With an immersion lens magnifying 750 diam., this was seen to be composed of a gelatinous mass in which were imbedded multitudes of globular *Micrococcus*-cells about 1 μ in diam. These presented all stages of transition between *Palmella mirifica* Rabh., and *P. prodigiosa* Mont. (*Micrococcus prodigiosus* Cohn, *Monas prodigiosa* Ehrenb., *Zoo-*

galactina imetropha Sette, or *Bacteridium prodigiosum* Schröt.); and Schnetzler believes Rabenhorst's *Palmella mirifica*, described as occurring in similar situations, to be but a form of Cohn's *Micrococcus prodigiosus;* the differences in the size of the cells and in the coloration being due to its occurrence on an animal instead of a vegetable substratum. The presence or absence of a gelatinous matrix is no distinctive character between the two species. During the formation of the red gelatinous matter on the meat, the temperature varied between 25° and 30° C. Cold alcohol extracted the colouring matter; the rose-coloured solution became greenish yellow on addition of ammonia, acids colouring it red. Spectrum analysis showed a broad absorption-band in the green.

We have therefore here a chromogenous Schizomycete which possesses the remarkable property of producing colouring matters from the elements derived from the substratum and from the air at a suitable temperature.

New Bacterium sensitive to Light.[*]—Among the Schizomycetes which T. W. Engelmann has previously studied, with respect to the action of light, only one was sensitive to this action. This form, called on account of its colour, *Bacterium chlorinum,*[†] disengaged oxygen in the light, and probably for this reason was attracted to the light when oxygen was deficient. He found, last year, a second form *Bacterium photometricum*, which reacted in a very high degree under the influence of light. It is slightly reddish in colour. The microspectroscopic eye-piece shows a powerful absorption of all the rays whose wave-length is less than $0·62\ \mu$, especially those between $0·62$ and $0·59$ (orange).

The influence exercised by light on *B. photometricum* differs very remarkably, in many respects, from that shown by other motile organisms.

In the first place the *rapidity of the movements* depends on it.

In *light of constant intensity* the rapidity of the movements is, generally, in direct proportion to the luminous intensity; more rapid, *ceteris paribus*, in the ultra-red and orange of the light of the sun or of gas, than in the other regions of the spectrum.

In the case of *prolonged action of light*, especially of an intense light (and chiefly of the ultra-red and orange), the greater number of the bacteria become quiescent, this taking place directly when the ventilation is imperfect. This repose may be disturbed (all the quicker when it has been of shorter duration) not only by darkening, or a change of colour which acts in the same way, but also by any appreciable increase of light.

When the *luminous intensity diminishes suddenly*, or when its *quality* (the wave-length) undergoes a change acting in the same way, the bacteria quickly retire, then stop for a time, and presently recommence their movements.

The *positive changes of the intensity or of the colour of the light* do

no more than accelerate the movements, even when they are very great and rapid.

The *direction* of the movements of progression changes in proportion with the *intensity* and *colour of the light*. In general, the bacteria move from less illuminated points to those which are more so, or from less active rays to those of greater activity. The converse only takes place when the luminous action is very intense. This results as much from experiments with glasses and coloured liquids as from observations in the objective microspectrum.* In this spectrum, the bacteria accumulate chiefly in the ultra-red and in the orange-yellow. A third maximum (much weaker) is found in the green.

In the spectrum of gas-light, the accumulation in the ultra-red is much stronger than that in the yellow; in the spectrum of solar light, the ultra-red only possesses a slight advantage in this respect. The crystalline lens and the aqueous and vitreous humours of four bullocks' eyes in a fresh state, having been placed in a series between the gas-flame and the microspectral apparatus, this intercalation had no perceptible influence on the accumulation in the ultra-red; it was the same on interposing a solution of alum in thick layers.

The *direction of the incident light* appears to have little or no direct influence on the direction of the movements.

Engelmann at first supposed that *B. photometricum* disengaged oxygen under the influence of light, and that the phenomena described might be essentially referred to modifications in this production of oxygen; but this presumption has not been verified. It has been impossible to prove a disengagement of oxygen. The bacteria are also, relatively, but little sensitive to differences in the tension of the oxygen; nevertheless, the increase of this tension acts, in almost all respects, in the same way as the increase of the light, and *vice versâ*. The addition of a little CO_2 acts in the same manner as a sudden darkening.

What seems most probable is that light excites in bacteria a specific chemical process of a reducing character, a process comparable consequently to assimilation. Special experiments have shown that the action of the light cannot be attributed to changes of temperature.

Connection of the Bacilli of Hay and of Distemper. † — In pursuance of his experiments on the mutual conversion into one another of the bacilli of distemper and of infusion of hay, H. Buchner reports the following results of experiments.

The original form from which the distemper-bacilli were obtained, the bacterium generated in infusion of hay, and distinguished by the name *Bacterium subtile*, is marked by an extraordinary power of resistance to high temperature, and by having no power of causing fermentation; requiring, therefore, for its nourishment free oxygen. The distemper-bacteria retain their infectious properties as long as desired at a temperature of 25° C. in solution of extract of meat,

* See this Journal, *post*, p. 661.
† SB. Akad. Wiss. München, 1882, p. 147. See Naturforscher, xv. (1882) p. 251. Cf. this Journal, *ante*, p. 89.

where they have the form of cloudy masses at the bottom of the perfectly clear nutrient fluid. If the temperature is raised to 36°, and the supply of oxygen increased by shaking, they multiply more rapidly, and at the same time gradually lose their infectious properties.

In order to convert the distemper-bacteria rapidly into hay-bacteria, the solution which contains them is shaken up violently, to increase the supply of air, in a vessel to the sides of which pieces of filtering paper are stuck. Three transitional forms are thus obtained, which finally pass over into the bacteria of hay. The change is greatly promoted by the addition to the solution of extract of meat, of yolk of egg, and a small quantity of alkali. After standing for about 24 hours at a temperature of 36° C., a transitional form, the bacteria of white of egg, is obtained, which, in a slightly acid infusion of hay, is transformed into the innocuous hay-bacteria.

The following is an epitome of the behaviour of these three inter-changeable forms of bacteria, which Buchner regards as adaptive forms of one and the same organism, *Bacterium subtile* :—1st medium. 1 per cent. extract of meat—(*a*) distemper-bacteria : solution clear, clouds at the bottom; (*b*) white-of-egg-bacteria : solution cloudy, floccu-lent, a mucilaginous pellicle, flocks and pieces of pellicle at the bottom ; (*c*) hay-bacteria : solution clear, with a firm, white, dry pellicle diffi-cult to submerge. 2nd medium. Slightly acid infusion of hay. (*a*) no increase ; (*b*) formation of a sparse white rim on the surface of the fluid ; (*c*) dry pellicle, moistened with difficulty, and usually with a wrinkled or pulverulent appearance. 3rd medium. The bodies of animals. (*a*) Infectious in very small quantities, producing dis-temper ; (*b*) when multiplied a thousandfold, inactive ; in still greater quantities, infectious, producing distemper ; (*c*) inactive even when present in the greatest quantities.

Diffusion of Bacteria.—The researches of Pasteur and Darwin have shown how earthworms may aid the diffusion of small organisms, some of which may produce disease. Professor J. B. Schnetzler states that the dejections of earthworms always contain numerous living bacteria and their germs (the hay-bacterium included). It is clear that bacteria in enormous quantity float in the air about us ; and we have at easy command, Professor Schnetzler points out, a small apparatus traversed by about 8000 cubic centimetres of air per minute, which may inform us as to those floating germs. This is no other than the nasal cavity, on the mucous surface of which air-particles are de-posited. To observe these he advises injecting the nose with distilled water (completely sterilized) by means of a glass syringe previously calcined. The liquid so obtained is put in one perfectly clean watch-glass and covered by another. With a Microscope magnifying 700 or 800 one finds, among various particles in the liquid, some real live bacteria. If the liquid be kept a few days in a clean glass tube hermetically sealed the bacteria are found to have increased very considerably. One sees *Bacterium termo, Vibrio, Spirillum, Bacillus subtilis*, even some *Infusoria*, and spores and fragments of fungi.

Professor Schnetzler has further successfully cultivated the organized germs by means of a mixture of gelatine and distilled water. Why do not these bacteria in the nasal cavity always multiply and develope and penetrate to the windpipe and lungs? Their progress is doubtless opposed by the vibratory movements of cilia in the air-passages, and the weakly alkaline reaction of the nasal mucus may (it is also suggested) be unfavourable to some of them. Cohn has proved that bacteria producing acid fermentation perish in liquids with alkaline reaction. Infectious bacteria may, however, multiply to a formidable extent on living mucous surfaces; witness the growth of the micrococcus of diphtheria, brought by the air into the air-passages; also the bacterium of anthrax. The bacillus of tubercle, as Koch has lately shown, may be transmitted from one person to another by the air-passages. Professor Schnetzler thinks hay fever may also be due to bacteria entering the nose. While the development of bacteria on normal mucous surfaces is usually limited, millions of them are found in the dejections of healthy children.

Parasite of Malaria.* — From observations on a considerable number of malaria-patients, M. Richard is able to state that in all cases a specific organism is present. It inhabits and undergoes development in the red corpuscles of the blood; the first indication of its presence within the corpuscle is a pale spot which grows and developes black granules at its periphery; it ultimately occupies the whole interior of the corpuscle, and then it ejects a collar with dark granules, and one or more delicate marginal processes; this is the parasite. It often oscillates with great energy for about an hour, even when not quite free from its host. The collar breaks up and sets free the granules which may be taken up by the white corpuscles. The "body No. 1" of Laveran appears to be a corpuscle containing a parasite whose development has been arrested. The comatose stage of the disease is produced by the blocking of the cerebral capillaries by blood-corpuscles containing parasites, in which condition they are very viscous and have lost their usual great elasticity. The appearance of the corpuscle when affected appears to demonstrate the existence of an investing membrane outside it. When the parasite is not abundantly present, Richard uses acetic acid to destroy the normal corpuscles, thus leaving the few affected ones readily visible.

Parasitic Character of Cases of Malaria.†—A. Laveran's account of this matter should be compared with that of Richard given above. He describes from the blood of malaria-patients three forms of parasitic elements.

1. Cylindrical bodies, with filamentous extremities, usually crescentic; length $8-9\ \mu$, diameter on an average $3\ \mu$. Contour marked by a very fine line; body transparent and colourless, except at the middle, where there is a blackish spot composed of very dark red

* Comptes Rendus, xciv. (1882) pp. 496–9.
† Ibid., xciii. (1881) pp. 627–30. Cf. Rev. Internat. Sci., iv. (1881) pp. 459–61.

pigment-granules. A very fine line is sometimes observed at the side of the cavity, and apparently serves to support the extremities of the crescent-shaped body. No movements appear to take place. The form is sometimes oval; and when it is but slightly elongated and the granules arranged in a circle, it closely resembles the other two forms. 2. Spherical transparent bodies, of the average diameter of a red blood-corpuscle, with pigment-granules often arranged in a circle when the body is inactive; in movement, they are agitated vigorously and become irregular in arrangement. At the margins very delicate filaments, slightly inflated terminally, often appear to be inserted; they move rapidly in every direction; they have a length of from three to four diameters of a red corpuscle; three or four may occur upon one body; they cause an oscillation of the body, and displace adjacent blood-corpuscles. They finally become detached from the spherical bodies, and then range freely among the blood-corpuscles. 3. Spherical bodies of irregular form, transparent or finely granular, 8–10 μ in diameter, containing rounded pigment-granules of a very dark red colour, sometimes arranged regularly near the periphery, sometimes aggregated at the centre or near the periphery. They are immobile, both as wholes and in their parts. They have been observed to result from the transformation of the body No. 2, and are probably the form which it takes at death. They have no nuclei, and are with difficulty stained with carmine. 4. Spherical transparent bodies like (2), but much smaller, viz. the smallest scarcely the $\frac{1}{6}$ of a red corpuscle in diameter, and containing only one or two pigment-granules each; the largest have almost the diameter of a red corpuscle. They occur either free or aggregated variously or attached to blood-corpuscles and appear to represent a phase in the development of the above parasitic bodies. Besides these four types, there occur red corpuscles exhibiting perforations and pigment-granules, dark leucocytes, and free pigment-granules of various sizes.

Out of ninety-two cases of palustric diseases of different kinds, these parasitic elements were detected in forty-eight, and their absence in many of the remaining ones may be due to the action of sulphate of quinine which had been administered to most of these, and which has been ascertained to have the power of destroying the parasite in blood removed from the body. The bodies cannot always be detected, they are most readily obtained just before the attack of fever and at its termination; in chronic cases, they sometimes exist permanently in the blood. In the intervals between the attacks they probably lie in the internal organs, especially the spleen and liver. Pigment-bodies always occur in great numbers in the blood, especially of the small splenic and hepatic vessels, of subjects that have died of palustric affections. When death takes place owing to accidental circumstances, the bodies are found in such quantities in the blood as to tinge the spleen, liver, marrow of the bones, and sometimes the grey matter of the brain, a brownish, quite characteristic colour. Thus the dangerous symptoms of malarial

diseases are produced by parasitic elements which occur under different forms in the blood.

Vaccinal Micrococci.—M. Straus presented to a recent meeting of the Société de Biologie at Paris a series of microscopical preparations of the vaccinal pustule from the calf, at different stages of its progress, in which the presence of the special micrococcus could readily be observed. The method of preparation adopted was to place the excised fragments of skin in absolute alcohol, to cut sections and stain them by Weigert's method (methylamine violet), and then discolouring them until only the nuclei, the bacteria, and micrococci remain visible. Under a high power, the latter were visible as extremely minute points, tinted blue, about a thousandth part of a millimetre in diameter, and grouped in colonies. They were seen in the borders of the inoculation wound, and in the Malpighian layer, and subsequently could be traced passing into the subjacent cutis, especially in the lymphatic spaces. The multiplication and extension of the organism seemed to coincide closely with the development of the pustule.

Mucorini.*—Professor G. Bainier has published a useful monograph on these fungi. In a general introduction he briefly considers the systematic position of the Mucorini, their reproductive organs, mode of life, and methods and results of cultivation. The bulk of the work is occupied with the description of the species, twenty-seven of which are figured. It concludes with remarks on the importance of the Mucorini in the economy of nature.

Algæ.

Disengagement of Oxygen by Vegetable Cells in the Microspectrum.†—T. W. Engelmann describes experiments on this subject. He has studied the relation between the wave-length and the assimilative action of the luminous rays by the " bacteria method." ‡ For this purpose he has made use of a microspectral apparatus, constructed under his directions by Zeiss of Jena. The apparatus forms a microspectrum at the plane of the object on the stage, and replaces in use the ordinary illuminating apparatus (mirror and diaphragm) of the Microscope. It is composed of, 1st, a plane mirror; 2nd, an arrangement with two slits, viz. *a*, a slit, with *both* sides movable by means of a micrometric screw and the breadth of which can be adjusted (with a range of 2 mm.) to about ·001 mm. *b*. A slit movable, perpendicular to *a*; 3rd, a collimator lens; 4th, a direct-vision prism; 5th, an objective forming the spectral image of the slit. As it is useful to be able to vary the absolute size of the

---

† Rev. Internat. Sci. Biol., ix. (1882) pp. 465–7. Pflüger's Arch. f. Physiol., xxvii. (1882) p. 485. Bot. Ztg., xv. (1882) pp. 419–26 (1 fig.).

‡ See this Journal, i. (1881) p. 962.

spectrum, it is advisable to have several different objectives. The sharpness of the spectra is such that some hundreds of Fraunhofer lines can be made perfectly visible. The luminous intensity, even when an ordinary gas-flame is used, is sufficient with a slit of 0·01 mm. wide to observe bacteria under a high power. By replacing the prism by a grating, the apparatus may also be adapted in a simple manner to the formation of a microscopic *interference* spectrum. The results now communicated were obtained by means of the *prismatic* microspectrum. The first question examined was that of the relative extent of the disengagement of oxygen by the green cells in the different regions of the spectrum. In this examination two methods can be adopted, viz.—1. The method of simultaneous observation. 2. The method of successive observation.

Simultaneous Method.—This consists in observing simultaneously the action of the different rays of the spectrum on different juxtaposed points of the same object. The object should have a regular structure. *Confervæ, Oscillariæ*, and some diatoms, are especially suitable. The object is placed in a transverse position in the microspectrum, that is, perpendicularly to the direction of the Fraunhofer lines. The following are the phenomena then observed.

When the luminous intensity increases, starting from zero, the bacteria in repose in the immediate neighbourhood of the green cells begin to move first of all in the *red*, most frequently between B and C, and nearer to the latter. Increasing the intensity of the illumination, the action extends on both sides to the commencement of the ultra-red and as far as the violet. The accumulation of the bacteria and the rapidity of their movement, remain in the beginning at their maximum in the red. With green cells (*Euglena, Œdogonium, Cladophora*), but not with brown (diatoms) and blue-green (Oscillariæ), there appears in sunlight (not in gaslight) a minimum in the green about E and a second maximum about F. When the bacteria are numerous, we see in such cases a kind of graphic representation of the relation between the wave-length and the assimilative energy, in which the abscissæ are represented by the object and the ordinates by the respective depths of the layer of bacteria.

In the case of very great luminous intensity the differences are reduced, because then the accumulation and the rapidity of movement become very great at all points.

If, starting from the maximum, the luminous intensity decreases gradually, the different aspects just described are reproduced in inverse order.

Successive Method.—In this method the object (preferably very thin) is placed successively in different parts of the spectrum, determining each time the narrowest width of the slit at which the bacteria begin to move. The results confirm in general those of the first, as is shown by two tables given by the author.

In one respect, viz. the situation of the maximum, the results of Engelmann differ very remarkably from those hitherto obtained by macroscopic methods by the best observers (Draper, Sachs, Pfeffer). These authors attribute to the *yellow* rays the strongest assimilative

action.[*] This difference depends, he thinks, specially on the fact that with the previous methods it was necessary to operate on entire plants or leaves. We then have to deal with a greater or less number of superimposed layers of chlorophyll. Those chlorophyll-grains alone which are nearest to the surface receive the light almost unaltered ; on those which are deeper down the absorption produced by the first makes its influence felt. But this absorption is chiefly exerted, as is already proved by the microspectral analysis of a single grain of chlorophyll, on the rays between B and C, which, according to Engelmann's experiments, are precisely those which are the most active, as well as the blue at F. On the other hand, the oxygen disengaged by the superficial chlorophyll-grains being generally only a small fraction of the total production of oxygen in the plant, it follows that the maximum action of the whole plant can no longer fall between B and C (and at F), but must be displaced in the direction of the green.

The justice of this view has also been proved by experiments in which the light, before falling on a cell, has to traverse a thin layer of a solution of chlorophyll. With certain thick cells, very rich in chlorophyll (*Cladophora* for instance), the densest accumulation and the most rapid movement of the bacteria may be seen to be *above* the cell towards the yellow, and *below* the cell in the red.

Disengagement of Oxygen by Hæmatococcus.[†]—The question whether the red unicellular algæ can assimilate without chlorophyll has been lately decided by J. Rostafinski [‡] in the affirmative, for reasons, however, which are not conclusive. T. W. Engelmann has examined this question by the bacteria-method, [§] and has obtained, even with specimens of a pure red apparently completely destitute of chlorophyll, a very marked reaction on the bacteria. The disengagement of oxygen was often tolerably brisk, especially in red light. The comparison of a great number of specimens of different colours showed however that, *ceteris paribus*, the disengagement of oxygen was so much the more considerable according as there was the more yellow or green observable in the colour of the cells. This gives rise to the presumption, that, even in cells apparently containing only red colouring matter, chlorophyll may still exist. By means of the microspectroscopic eye-piece of Zeiss, it has been found that there is in the spectrum of these cells a dark space corresponding to the chlorophyll-band between B and C. In the cells of the purest red this band was faintly visible only with a particularly favourable illumination ; it became more distinct in proportion to the greener appearance of the cells.

In view of these facts, it must be admitted that the above-mentioned absorption-band does not belong to the red colouring-matter, but arises from chlorophyll associated with this matter, and it may be considered as very probable that even the entirely red individuals of the genus *Hæmatococcus* only assimilate because they still contain chlorophyll.

* See amongst others, Pfeffer, 'Pflanzenphysiologie,' i. (1881) p. 211 *et seq.*, fig. 29.

§ See this Journal, i. (1881) p. 962.

Hydrurus.[*]—J. Rostafinski gives the following diagnosis of this little-known genus of algæ, which forms brown slimy flocculent masses in cold rapidly flowing water :—" Thallus hydrobius, lubricus, disco conico affixus, elongatus, usque ad tres decimetros longus, ex uno podio principali, in medio latissimo, ramos laterales emittens; inferne simplex, plerumque nudus, primo intuitu gelatinosus, in tactu duriusculus sed elasticus, solidus aut rarissime senilitate canescens; semipellucidus, ochraceus; superne aut simplex aut penicillatus, varioque modo divisus; semper tota sua superficie, ramulos minores filamentis tenuissimis obtectos, ex olivaceo fuscos aut nigros producens."

The peculiar mode of reproduction takes place only by night. The lower branches of the thallus begin to swell, and the gelatinous matrix of the cell-walls deliquesces and at length altogether disappears. The brown endochrome, previously in the form of bands or caps, collects into globular bodies which at length pass into a tetrahedral form, furnished with projecting ridges or beaks. These develope directly into a new thallus.

The nearest ally of *Hydrurus* is Woronin's genus *Chromophyton*,[†] which does not necessarily inhabit the leaves of *Sphagnum*. The two genera agree in their gelatinous deliquescent cell-walls; but the reproductive bodies of *Chromophyton* have more the character of zoospores. Rostafinski proposes to unite them into a new family under the name Syngeneticæ.

Relationship of Palmella to the Confervaceæ.[‡]—Colonies of *Palmella uvœformis* Ktz., gathered by J. B. Schnetzler in a small stream near Lausanne, were found to be composed of minute cells, about 0·01 mm. in diam., congregated into a gelatinous mass. Placed in spring water, and covered with a watch-glass, they produced zoospores, which swam about with great activity, and finally formed a green coating on the sides of the glass. After a time they germinated, and developed into a green alga composed of branched filaments of elongated cylindrical cells with lateral excrescences. Similar filaments also developed directly from the gelatinous cells of the *Palmella*. On evaporating, the cells separated from one another, assumed a globular form, and transformed themselves back again into gelatinous colonies of *Palmella*. The filaments thus produced were a *Stigeoclonium*, or some nearly allied confervaceous alga. The water-bed in which the *Palmella* was originally found was sometimes full of stagnant or running water, sometimes completely dry; at that time the alga was accompanied by quantities of diatoms and by crystals of calcium carbonate.

These observations complete others previously made by Cienkowski and Famintzin on the disintegration of *Stigeoclonium* and of another confervaceous alga into *Protococcus*-cells, which have led Kützing and

others to the conclusion that the genera *Palmella*, *Protococcus*, and *Pleurococcus* are simply phases in the cycle of development of higher algæ.

Division of Closterium intermedium.*—J. Schaarschmidt describes the mode of division of this desmid as analogous to that of *Penium interruptum*. It has a primary suture, and a secondary suture in the middle of each hemicyst; and these present structures similar to the caps of *Œdogonium*. Before each division the cuticle is raised from the cell-wall in the form of a ring hollow on the inside, which splits on division, while the very plastic cell-wall rapidly stretches. The number of secondary and tertiary sutures, &c., may be very considerable, the author having noticed as many as twenty-four rings, indicating the number of times that the individual divides. He believes that all other species of *Closterium* with secondary sutures divide in the same way.

Diatoms from the Island of Lewis.—Mr. E. W. Burgess sends the following list made from the examination of a diatomaceous deposit, new to Great Britain, from the island of Lewis, near Stornoway, which he thinks may be of interest to those working out similar deposits. It was found in the possession of J. Thompson, who was using it to polish sections of corals. The list has been submitted to Dr. Stolterfoth, of Chester, for verification of most of the species.

Abbreviations:—*vr.* (very rare), signifies that only one or two valves have been found; *r.* (rare), about one on each slide; *c.* (common), three or four on a slide; *vc.* (very common), the form most often met with on the slides. Prof. H. L. Smith's arrangement has been followed.

MICROSCOPY.

a. Instruments, Accessories, &c.

Bausch and Lomb Optical Co.'s Professional Microscope.—Fig. 113 (sent from America, and one of the best woodcuts of a Microscope which we have seen) shows the "Professional" Microscope of the above Company.

Its specialities are the frictionless fine adjustment (described at p. 683), the glass stage and slide-carrier (described at p. 687), the centering of the substage (of which we have no detailed description), the two draw-tubes which allow of more than the ordinary variations of length, and the mirror and substage bars which are separate and can be moved independently of one another, or simultaneously when the arm on the mirror is placed in a recess in the substage bar.

Bulloch's Newer Congress Stand.*—This (Fig. 114) is made upon the original plan,† with the exception of the stage, the construction of which has been modified.

The stage (Fig. 115, Nos. 1-4) is held by a saddle-piece which is steadied by a strong brace passing down from the limb.   It is entirely independent of the swinging of the mirror and substage.   This saddle-piece contains a set of screws with perforated heads for centering the ring which supports the stage.   These screws are so far back that the ring can be made very thin without reducing the strength or rigidity.   The stage rests upon this ring.   It rotates, and can be accurately centered by the screws in the saddle-piece.

This stage is a revival of an idea which Mr. Bulloch says was used by Spencer thirty years ago.   It consists of the ordinary stage-plate, having in its centre a large square hole.   One side of this plate contains a wide dovetailed groove, in which slides a bar with its surface level with the top of the plate.   At right angles to this bar is attached another bar.   On this second bar slides a third bar, into which it has been dovetailed.   The motion of this third bar is at right angles to the motion of the first.   A thin plate is attached to the third bar, and lies flat upon the stage-plate.   This plate is perforated, and holds the slide by means of a spring.   It will be seen that this arrangement permits of motion of the thin plate in two directions at right angles to one another.   Two pinions, perpendicular to the stage, control

* Cf. 'National Scientific Journal,' i. (1881) pp. 230–1 (5 figs.).
† See this Journal, iii. (1880) pp. 1076–8.

Fig. 113.
FIG. 114.
this motion; they work one through the other, and act upon racks placed at right angles. Scales placed at right angles serve as finders.

Fig. 115.
The substage is similar in design to that of Messrs. Sidle, described *ante*, p. 555, and a screw has been added to the base for clamping the base-plate which rotates on the tripod.

Guillemare's School Microscope.[*]—This (Fig. 116, $\frac{1}{3}$ nat. size) is the design of Professor A. Guillemare, of the Lycée Charlemagne, Paris, and is apparently intended for junior pupils, its speciality being the screws V and V, by which both the tube and the slide are locked, so that they can only be freed by the professor with the aid of the key shown in the woodcut.

[*] Journ. de Microgr., vi. (1882) pp. 233–5 (1 fig.).

The handle M, by which the instrument is held when passed round a class, is hollow, so that it can be placed on a vertical support, if desired. C is a metal cone polished inside, and we gather that at

Fig. 116.
P is the arrangement for fine focussing after the tube has been adjusted as nearly as possible and locked.

Gundlach's College Microscope.—This Microscope, till now called the "Physician's Microscope No. 1," is shown in Fig. 117. Its speciality consists in the *adjustments*, of which there are four, thus described (from the maker's catalogue):—

"(1) A rack-and-pinion movement; (2) a sliding adjustment of the body; (3) a micrometer-screw, and (4) a combination of micrometer-screws giving a slower motion than has ever been brought into use before. The racks and pinions are cut with some new and original tools and with the greatest exactness.

"Gundlach was the first to think of the advantages of the combination of the sliding adjustment with the rack and pinion, and to bring out a series of Microscopes on this plan. The former allows the body to be removed for changing objectives; and, by combining the two, the body may be made to stand so high that first-class low-power objectives may be used on these stands. Lower powers may be used on them than most large stands will allow.

"The ordinary fine adjustment is by micrometer-screw acting on Gundlach's new frictionless roller motion, patented in 1879. This motion is free from the fault of displacement of the optical axis, from so-called loss of motion, and from lateral motion, while it has twice the old extent of motion. . . . .

"In working high powers, microscopists have felt the need in some work of a slower motion than that of the ordinary micrometer-screw, which cannot be made much finer and still be durable enough. This need is now supplied by the combination of two screws which give a resultant motion equal to the difference in the threads employed. One of these screws is a little coarser than the ordinary micrometer-screw, and may be used alone as a fine adjustment, and a change can be made instantly from this to the finer motion. Either motion is given by one milled head next to the top of the pillar, and the change is made by turning a smaller clamping screw having its head over the

fine adjustment screw. By tightening the clamping screw, the adjustment is in order for the work of the combination; by loosening, for that of the coarser screw only. As the thread of this is a very little coarser than the ordinary micrometer-screw, it alone gives a better motion for medium powers than the fine adjustment in common use, a second advantage of the invention. The combination of screws in use on these Microscopes gives a motion equivalent to that of a screw having three hundred and sixty threads to the inch. Any desired combination can be made."

FIG. 117.

The *stage* consists of a strong, polished glass plate, made secure by a brass frame, which is nickel-plated. The glass plate has a hole in the centre, and is ground to permit the greatest obliquity of light. A new object-carrier, consisting of an ornamented brass frame, with a rest for the object-slide, removable clips, and two handles, moves with evenness upon the stage, to which it is pressed by lever springs, with double joint, to permit motion in every direction, and from which it is kept by frictionless pins that do not scratch the stage. The whole carrier can be removed and its place supplied with spring clips.

The *substage* slides along the mirror-bar, thus keeping the diaphragm or other accessory concentrically with the mirror upon the object with central as well as oblique illumination. It can be removed without interfering with the mirror.

The *diaphragm* is of novel construction, and is fitted to the sub-stage. It is of such form that it can be brought close to the slide, and its openings brought in use without changing its position on the mirror-bar.

The *mirror-bar* swings to an angle of 45° above the plane of the object, allowing the mirror to be used as a condenser on opaque objects. The mirrors have their centre of motion around the point where the optical axis intersects the plane of the object.
Martens' Ball-jointed Microscope.*—This (Fig. 118) is the invention (patented) of A. Martens, of Berlin, and is thus described :—

In the observation of metals in their microscopical relations it is desirable to be able to give the Microscope the greatest possible power of movement, since the objects for the most part do not admit of small fragments being taken from them. A Microscope was originally made for the author by Zeiss, in which movability of the stand was obtained by three hinge-joints, which could be clamped up by a screw so that the tube remained quite firm at every angle ; indeed it was firm enough to admit of a fine adjustment being used. It was, however, too limited in its action, it worked properly only in a line perpendicular to the object, and in order to examine the neighbouring parts either the heavy object or the equally heavy instrument had to be moved.
Fig. 118.

In the new construction the inventor has obtained far greater movability. Instead of the hinges, ball-joints of large diameter are made use of, the balls being hollow and clamped between two annular plates, placed unsymmetrically with regard to the centre of the ball. The plates are forced together by the action of a screw, a strong spring between them separating them again when the pressure of the screw is slackened. Thus a clamp, firm but readily loosened, is obtained. One or more ball-joints can be used for each stand.

Polarizing Microscopes.†—Prof. J. B. Listing objects to the term "polarizing Microscope," so commonly applied to the Nörremberg (or Hofmann) polarizing apparatus. The use of the name "Microscope" is not only incorrect in itself but it conflicts with that which properly belongs to a Microscope by means of which small objects are examined by polarized light, such as sections of minerals, crystals, hairs, muscle-fibres, &c. The objective of the true polarizing Microscope retains its ordinary dioptrical function, but in the other case no question of amplification comes into consideration (but rather a large angular diminution), the instrument without the lower collecting-lens being in reality an inverted astronomical telescope with the eye-piece turned to the object.

* Zeitschr. f. Instrumentenk., ii. (1882) p. 112 (1 fig.).
† Bericht wiss. Apparate Lond. Internat. Ausstellung im Jahre 1876 (A. W. Hofmann, 1878–81) pp. 367–8.

Schieck's Microscope with Large Stage.[*]—Prof. G. Fritsch writes that F. W. Schieck deserves special commendation " for constructing stands which, in regard to the size of the stage, very considerably exceed the ordinary dimensions without being either clumsy or unsightly. The ever increasing necessity for examining preparations of large size (such as sections of brain), or series of preparations on large slides, make such stages a pressing necessity." Fig. 119 shows one of these stands with a stage 14 cm. wide. To prevent the slide from falling over the sides when moved to the furthest extent, two arms are attached to each side, the upper surface of which is on a level with the stage. When not required they can be turned back close to the sides of the stage.

FIG. 119.
Projection-Microscopes.[†]—Dr. Hugo Schröder, in an interesting paper on lantern or projection-Microscopes, points out that the oldest forms originated in the earliest times of microscopical observation, when the whole magnifying apparatus consisted of a simple bi-convex lens with very small aperture. In consequence, the images had great depth, so that relatively thick objects were shown with distinctness. The images, however, by lamplight were exceedingly dim, if the power amounted to 100 or more. This was not, however, the only defect arising from the very small aperture, for the resolving power was also very insignificant, and the image was injuriously affected by the chromatic and spherical aberrations of the objective-lenses. As the result of these and other defects, the instrument was so unsatisfactory with regard to distinctness of detail that the same objective-lens was more efficient when used as a simple magnifying-glass.

It will therefore be naturally asked in what consists the usefulness of the projection-Microscope ?

Its utility is to be sought in quite another direction, and under certain circumstances it becomes highly important, if not indispensable. For purposes of demonstration there is nothing better than a good projection-Microscope. Many persons can examine the object at the same time, and a larger field of view can be obtained than would be possible with any other combination. The angle of the image, which in the compound Microscope is at most 10°, can be increased to

* Bericht wiss. Instrumente Berliner Gewerbeausstellung im Jahre 1879 (L. Loewenberg, 1880) p. 293 (1 fig.).
† Central-Ztg. f. Opt. u. Mech., iii. (1882) pp. 2-4, 15-17 (1 fig.).

40° or even to 60°, whereby, under equal circumstances, a 36-times larger surface can be viewed, and by 100 and more spectators. It is also very useful for pointing out to beginners particular parts of the object, in the same way as a drawing would be explained. The observation of the projected image requires no especial practice, as in the compound Microscope; and finally the image can be easily drawn or even photographed.

Notwithstanding all these advantages, however, these instruments —called by Professor Petzval the " *chef-d'œuvre* of optical art "—have hitherto been very hardly treated. Usually the lenses of a compound, Microscope (often most unsuitable) were employed, and illuminating lenses with surfaces exactly convex, thus constituting a very indifferent instrument. The necessity of employing a heliostat, and the difficulty of always obtaining sunlight at the required moment, gave an impulse to the construction of the so-called lantern Microscope used only with artificial light, and in the last century Adams was celebrated for such instruments, which could be used in several ways, as simple, compound or lantern Microscopes. Their performance was best as simple, moderately so as compound, and very inefficiently as lantern Microscopes.

Much later, when achromatic objectives were introduced, Chevalier in Paris and Duboscque constructed much more complete instruments, and in modern times Foucault invented the excellent photo-electric projection-Microscope.

At first sight nothing seems simpler than to construct a good lantern Microscope since we have only to replace sunlight by lamp-light. This is, however, not the case, for on further consideration it will be found that the conditions which are so favourable with sun-light cannot be maintained with any artificial light—we can only approximate to them. The intensity of all artificial illumination, even the strongest electric light, is considerably less than that of the sun; besides, all strong lights have far too large an illuminating surface to give distinct images with many fine details. The earlier lantern Microscopes had the worst possible illumination, for good oil-lamps did not then exist. If petroleum or gas lamps be used, it will soon be found that the magnitude of the flame in no way heightens the effect; although the image surface may appear to be more brightly illuminated, the contrast between the light and dark parts will be less—the absolute intensity is greater, but the relative smaller. If we follow the course of the illuminating rays it will be seen that the flame limits light diverging in all directions. Divergent light cannot, however, be employed for the illumination of an object, but we must always have convergent light. The source of light is therefore placed in the first focal point of a convex illuminating lens and the object in the second. The nearer a lens of given diameter is to the source of light, the greater will be the aperture-angle of the illumination; the greater the quantity of light utilized the further off will be the second focal point and the less the convergence of the rays upon the object. The convergence of these rays must, however, correspond with the final convergence of those which limit the field of view, and therefore, for all the rays falling on

the first illuminating lens to be utilized, a second condition must be fulfilled, viz. that the image of the source of light which falls on the object must not be larger than the object itself. Since the source of light and its image are as the two focal lengths it is obvious that these conditions can only be strictly fulfilled with very low powers and under very favourable conditions. With higher powers the greater part of the light is lost for this reason, that the intensity of the light with the higher powers diminishes not with the second, but approximately with the third power of the amplification.

The greater part of the light from the lamp does not fall on the first illuminating lens. In order to utilize as much of this portion as is possible the attempt has been made to concentrate by means of large concave mirrors the light which is lost on the side opposite to the condensing lenses. The mirror—which should be concave—must have the flame in its centre of curvature, the image of the flame, therefore, coinciding with the flame itself. As this is transparent, only a small portion is lost by absorption, and the part that is utilized follows the same direction as the other rays. This condition is absolutely necessary, in order to avoid lightnodes in the illuminating cone produced by two different converging rays, whereby the clearness of the image is materially affected. It is thus evident that with all ordinary flames only the segment of a small circular surface is utilized. The flat flames, the narrow edge of which is used (as for example in the Sciopticon), give the best results. On account of the too great extent of the illuminating surface, lighthouse lamps, which consist of a number of concentric wicks, only yield a very moderate result, notwithstanding the quantity and intensity of their light. Fresnel's ring-lenses are also unsuitable. Illuminating lenses of the smallest dimensions and the largest aperture angle (as near as the temperature of the flame will allow) give the best results. It is also advisable to insert a movable lens between the object and the illuminating system, in order to regulate the convergence of the light according to the requirements of the objective employed. To obtain a perfectly uniform illumination of the image-surface it is further necessary that it should not be the image of the source of light produced by the illuminating lens that falls on the object, but a neighbouring aberration-circle, in which the light is uniformly distributed. (Petzval has already drawn attention to this.)

Besides lamplight the Drummond lime-light has been employed very satisfactorily, and after many experiments Dr. Schröder considers it the best on account of the small and intensely illuminating surface of the lime and its pleasant light. In spite of its intensity, the magnesium-light gives no satisfactory result, because it does not burn steadily, and even when a ventilator is employed, the lenses are covered with the burnt magnesium. The electric light is excellent on account of its large intensity in a small space, but its unsteadiness is objectionable. The Jablochkow candle is most suitable, notwithstanding its small intensity, if a uniform height can be maintained. The incandescent light is too small in intensity, and too oblong.

If in course of time the electric light is more perfected a new epoch will commence for the lantern Microscope, and this highly interesting instrument, in a compendious form, will certainly not be wanting in any wealthy (*gebildeten*) family.

The objectives must of course be as free as possible from spherical and chromatic aberration, and must form a perfect image of the object, not only in and near to the axis (as in the ordinary compound Microscope), but over the whole extent of the image-surface, a by no means easy matter with large apertures.

Dr. Schröder has constructed a projection-Microscope for the Microscopical Aquarium at Berlin, and a considerably more improved one for North America, the first of which is shown in Fig. 120.

Fig. 120.
The source of light is at *a* ; *b* and *c* are plano-convex lenses of crown glass, between which at *p* an alum cell is interposed to intercept the heat rays. The rays emerge from *c* strongly convergent, but are made parallel and corrected for spherical and chromatic aberration by the combination *d e*. The parallel beam *s* is made convergent by the movable lens *f* according to the requirements of the field of view. For polarized light a large Nicol prism can be placed at *s*, and selenite plates at *u*. The analyser is attached to the objective.

By means of a silver prism *g* the illuminating beam is thrown upon the object *l* vertically " in order to admit of using receptacles for holding living animals in fluid, &c."

The objectives *m*, *m'* are attached to a revolving holder *o*, *o'*. Powers from 100 to 2000 can be used. They are focussed by the screw *n*, the upright piece *t* serving for revolving the holder when a different power is required.

The rays after having passed through the objective are reflected by a silvered prism *h* horizontally through the negative achromatic lens *h'*, and form an image at *q*.

The American instrument has immersion lenses giving a power of 4000 times, and can be used for opaque objects by means of a large Lieberkuhn.

"Notwithstanding the many reflecting surfaces," Dr. Schröder says that " with only an *ordinary petroleum lamp* the larger diatoms such as *Triceratium favus* can be very distinctly seen. With the oxy-

hydrogen light living diatoms and sections of plants are extraordinarily beautiful, all natural colours appearing very bright. With a power of 2000 the cornea of a fly occupies the entire field of view, and the fine vitreous membrane in each cell is seen magnificently."

Rock-sections can also be well shown in polarized light.

Apparatus for Projecting an Image to any required Distance with Variable Amplification.[*]—For lectures it is often desired to throw on the screen an image of an object with a given amplification, and in order to vary the amplification, several auxiliary appliances have hitherto been brought into requisition. A. Crova has devised a means by which, with the same distance of the object from the screen, the amplification may be changed with the aid of only one additional piece of apparatus.

He places between the object and the screen two lenses of equal focus, one plano-convex and the other plano-concave, their distance apart being capable of being altered as required. The plano-convex lens is fixed in a frame which is fastened to a horizontal brass rod resting on the stand, and along this rod the other lens (similarly fixed in a frame) is made to move by rack and pinion. The lenses have a focus of 0·15. By means of divisions marked on the rod the lenses can be set at the distance required; when the plano-concave lens is at zero the two lenses are completely in contact, and their optical centres coincide; according to the distance between the lenses the converging or diverging effect of the system predominates.

Waechter's Travelling Dissecting Microscope.[†]—This, Fig. 121,

FIG. 121.
by P. Waechter, of Berlin, is specially adapted for travelling, as when closed, it forms a box of only 10 cm. in length by 10 cm. in breadth and 7 cm. in height. The two halves of the cover *a*, opening right and left, serve as supports for the hand. Inside the box is the stand *b* with the stage and mirror, as well as the receptacles *c* for keeping the three achromatic objectives of 15, 25, and 40 power. The remaining space can be utilized for other apparatus.

Measurement of the Power of Eye-pieces.*—Dr. Royston-Pigott originally suggested the placing of the eye-piece in the sub-stage and throwing an image of a rule, supported at a distance of 10 inches from the diaphragm of the eye-piece, upon a stage micrometer. Mr. W. H. Bulloch having found considerable difficulty in getting the lines of the rule sharply defined, has devised an apparatus consisting of an ordinary Microscope with an objective of 2 inches focus, used to examine an image of a diaphragm, formed by the eye-piece to be measured. The exact size of the diaphragm and its distance from the eye-piece being known, the size of the miniature image formed by the eye-piece can be readily measured, and a simple calculation then gives the magnifying power.

Hall's Eye-protector for use with the Monocular Microscope.† —Dr. L. B. Hall describes an appliance to be used with the monocular instrument, for the purpose of protecting the unemployed eye, pointing out that the employment of one and the same eye at the tube of an optical instrument is the same practice that cost the squinting eye of childhood its power of vision. So many of us are contented at having trained one eye to do acceptable work, that we think we cannot spare the time to discipline the other. If this process ended when the head is withdrawn from the instrument, the practice would be less dangerous, but the trained eye finding an unequal companion, performs reading and all other near work with greater ease than its fellow ; sees so much more distinctly that the other is left without exercise, except for large objects, and becomes of less and less value as the process goes on. Dr. Hall could point, he says, to those who have practically lost one eye by this process, and estimates that one-half of all those who have used the monocular Microscope to any considerable extent during five years are monocular men for all fine work, meaning by this that every such person who can " resolve " one of the more difficult tests with one eye will find himself unable to do so with the other.

How often have we heard persons exclaim, upon looking into a binocular Microscope for the first time, how much easier it is to see with the instrument, and this with one field quite dark ; such expressions are not to be ascribed wholly to dissimulation or flattery, and for the following reasons, viz. :—When both eyes are left open and one is applied to an instrument, the two images, being unlike,

confuse each other in the natural endeavour to blend them. This requires a mental effort to exclude the impression upon the retina of one eye and regard that upon the other only. Again, when we close one eye by contraction of the orbicular muscle, or by pressure, as by the hand, we cause contraction of the accommodating muscle also, and of the other eye as well.

To facilitate the training of both eyes the following eye-protector is proposed. It consists of a small, opaque disk near the eye, supported by a wire extending from its outer edge downward, to a point on the tube low enough to be out of the way of the nose, then bent upward, parallel to the tube, but not touching it, and attached to a ring near the top. Dr. Hall's is made of a piece of brass wire, No. 18, about 45 cm. long; a loop at one end, 4 cm. in diameter, covered with a piece of black paper folded over and gummed down, forms the disk. At the other end is a ring to fit the draw-tube, and then the intermediate wire bent. It is attached below the flange, on the draw-tube, where there is no lacquer to be scratched, but if it should be thought desirable to attach it above the flange, then the ring ought to be covered with chamois, so as not to wear the polish.

The advantages of this form are, the small size of the disk and its support, interfering with the working of the instrument and view of the stage as little as possible. The support is not in the way of the nose; it is elastic, not uncomfortable when touched by the nose, and striking it does not displace the stand; it can be rotated about the tube and used with either eye alternately; it can be easily adjusted to the eye-distance of any worker; and, lastly, it is of so simple a construction that any one can make it for himself at a very small cost.

Cramer's Camera Lucida* (also Hofmann's and Oberhäuser's). —Dr. C. Cramer can only concur to a small extent in the warm praise which Dr. H. von Heurck has bestowed upon Hofmann's camera lucida.† Besides the advantage of having the paper lie

---

* Bot. Centralbl., vii. (1881) pp. 385–91 (2 figs.).
† Hofmann's camera lucida was described and figured in this Journal, ii.

Fig. 122.
(1879) p. 21. We, however, add here a diagram of it (Fig. 122), S being the silvered mirror over the microscope-tube, s^2 the smaller silvered mirror which
FIG. 123.

FIG. 124.
horizontally on the table, this camera lucida certainly shows the drawing-pencil with greater distinctness than any other similar instrument, that of Oberhäuser-Hartnack not excepted. For very long-sighted persons the two convex glasses placed below the two smaller mirrors may be of use, but for normal and short-sighted persons they are useless, and it is, moreover, better left to each individual to assist his sight by spectacles as required. The cap (with an aperture) over the two mirrors is also well adapted to serve as a guide to direct the eye of the observer, and thus facilitates its use by beginners, who often have a difficulty in finding the image. These advantages are, how-

receives the rays from S and reflects them upon a plate of glass s^1 and thence to the eye, the pencil being seen through the latter ($a\ b\ c\ d$ is the fitting which holds s^1 and s^2). There is a subsidiary apparatus formed of two plano-convex lenses for reducing the amplification.

Oberhäuser's (or Hartnack's) camera is shown in Figs. 123 and 124. It consists of two tubes A A at right angles, a rectangular prism d being inserted at the point of junction, by which the rays coming from the object are reflected through an eye-piece B f e to a smaller prism C, and thence upwards to the eye.

ever, counterbalanced by considerable defects. The sharpness of the image is impaired by the threefold reflection, which is effected partly by mirrors silvered at the back, and partly by the transparent mirror, the two surfaces of which produce images which of course do not coincide. By using still thinner mirrors this defect might be lessened but not removed entirely. The right and left sides of the object are inverted (though the image is otherwise erect), and this renders it difficult to a most tiresome degree for the microscopist, who is accustomed to the inverted motion of the object, to adjust it, and still more to afterwards correct complicated drawings by the ordinary microscopical image. Employing an orthoscopic eye-piece or inverting the drawing arrangements is of no use, as the microscopical image, compared with the drawing projected by the camera, appears in both cases with right and left hand parts interchanged.

The camera, moreover, will not bear the application of the blue glass disks supplied with the Oberhäuser instrument for modifying the light, as the image becomes almost invisible. As its characteristic, however, is the relatively great brightness of the surface of the paper, a smoked glass mirror, in place of the plain one s^1, would be the more serviceable arrangement, but the instrument is not constructed so as to allow such a change to be readily made.

The combination of lenses for the purpose of reducing the image is, the author thinks, a valuable addition. The insertion of the camera lucida is of course equivalent to lengthening the tube of the Microscope, and the image is strongly magnified, often too much so. It is only to be regretted that when both plano-convex lenses are employed simultaneously, the image, already obscure, becomes still less clear, and in some cases almost invisible. Dr. Cramer also draws attention to the fact, not thought of by Hofmann himself, that his camera lucida combined with the reducing apparatus, when inserted in the tube of the Microscope instead of the eye-piece, will give an image without the objective. The amplification with the two lenses is about four times. He considers that " if Hartnack could prevail upon himself to construct his camera lucida in such a way that in the short arm, or in place of it, a combination of lenses analogous to Hofmann's were introduced so that an image magnified only four to eight times could be obtained, the value of this instrument, already so desirable for the microscopist, would be materially increased."

Dr. Cramer then describes an instrument suggested by himself :—
" Those who use the Microscope, especially beginners, are not always in a position to buy a camera lucida. I think, therefore, that I shall be doing many a service by showing how any one who possesses a little mechanical dexterity may make for himself the very serviceable camera lucida shown in Fig. 125.

" It consists essentially of two somewhat diverging mirrors, one of which, S, allows the image of the object to be viewed direct through a circular hole made by removing the quicksilver from the under side of the mirror. By the second mirror, S', the rays from the pencil and

paper, which lies horizontally on the table to the right, are reflected to S, and thence upwards to the observer's eye. If the field of view is too bright, the light may be moderated by blue glasses placed in front of the illuminating mirror. The apparatus is attached by a wire pin to a ring R, made out of strips of paper, and can be readily detached when required.
FIG. 125.

"The ring should be made first, as it has to move with some friction on the upper end of the tube of the Microscope, and must exceed in diameter the upper rim of the eye-piece about 2‴. The eye-piece should be removed, and the upper end of the tube used as a mould for making the ring. The outer layers of the ring must be made higher than the inner ones by about the thickness of the upper rim of the eye-piece. This rim will thus fit into a corresponding depression in the ring. The aperture for receiving the wire pin is best made last of all, by the repeated insertion of a red-hot needle. This should be done with the eye-piece in place in the ring. After this, two rectangular plates should be cut out of an old mirror, the glass of which must not be too thick, and the coating of quicksilver should be scratched off from a central hole. Then attach by gum two pieces of card of the same shape and size to slightly larger pieces of note paper, and place the mirrors (after making a hole in one of the cards to correspond with that in S) with their backs downwards on the cards. Gum the projecting edges of note paper, turn them up, and press them down over the edges. Then make the trapezoid sides of the apparatus (also out of cardboard), and attach them to larger pieces of note paper so as afterwards to be able to glue them firmly to the backs of the mirrors. Cut two pieces the exact shape of one of the sides out of a cigar box for the purpose of strengthening the side turned towards the observer, which receives the wire pin. A pin of about 1 mm. thickness is quite sufficient. It should be bent twice at right angles, so that its two legs of unequal length are about the thickness of one of the two wooden boards apart. The longest leg passes between the card and one of the boards, and the other shorter one between the two boards which are to be glued together. Grooves must first be made in the boards corresponding to the thickness of the wire. The direction of these is easily settled by remembering that the pin must be placed exactly in the middle of the half of the ring turned towards the observer. The sides $a\,b\,c\,d$ must be in a horizontal plane, and the lower edge $e\,n$ of the mirror S (parallel to $a\,c$) must be exactly on the boundary between the lower and upper halves of the card ring.

"When all has been put together, it is well to increase the firmness

of the apparatus by pasting on an additional piece of card of the shape $b\,d\,f\,g$, and all the surfaces except the mirror should be blackened with indian ink.

"Dimensions:—$a\,b$ and $c\,d$, also $a\,h$, $b\,i$, $g\,k = 30$ mm.; $b\,g$, $d\,f$, and the corresponding sides of S $= 37$ mm. ; the mirror less by the thickness of the card—$h\,c$, $i\,d$, and $k\,f$ (in my apparatus made for Oberhäuser's eye-piece $= 10$ mm.) will vary according to the size of the eye-piece. Diameter of the hole in the mirror S $= 3$ mm. Distance of its upper edge from the left side of the mirror $= 19$ mm., angle $f\,d\,c = 157°$, $d\,c\,e = 36°$, $c\,e\,f = 130°$, $e\,f\,d = 37°$."

Bausch and Lomb Optical Co.'s Fine Adjustment.* — Fig. 126 represents the original of the fine-adjustment referred to at Vol. I. (1881) p. 110. Two strong parallel blades of finely tempered steel, $a\,a$, are securely fastened on one end to the back of case d, on the other to the arm e, which carries the rack and pinion. b shows the micrometer screw, which is fitted to the upper part of the upright arm c, f is the pinion, g the rack and slide, h the tube. Two screws fasten the adjustment case d to the pillar c. An arm projects from the part e and passes into a recess in the pillar c. The springs support the entire body, and as their tension is upward, the projecting arm bears continually against the micrometer screw b, and it is evident that the distance traversed by the screw involves the same movement of the arm e, and consequently the body. The only points of contact are at the ends of the springs a, a, where they are fastened respectively at d and e, and on the micrometer screw, and as in the former there is absolutely no friction, there is no wear; while that which may eventually take place in the latter is taken up by the force of the springs.
FIG. 126.

The points of excellence claimed by the makers for this adjustment over all others, are the following:—

* From the Company's Price List, 7th ed., 1882, pp. 4–5 (1 fig.).

"1. It moves the entire body.   2. It is extremely sensitive and direct.   3. It has no lateral motion or displacement of the image, while adjusting.   4. It has absolutely no lost motion.   5. It can in no manner deteriorate."   The "Professional" Microscope (shown at

FIG. 127.

TEN EYCK N.Y.
Fig. 113, p. 667) has the fine adjustment in the form above described, while in the "Model" Microscope of the same makers (Fig. 127) a slight variation is made by the bar *e* being placed below instead of above.

Nose-piece for Binocular Prisms.—When the broad gauge ($1\frac{1}{4}$ in.) screw is used (for low powers of wide angle), it is necessary to provide some means, not merely for the withdrawal of the prisms of the binocular, but for the removal of its fittings so that the end of the tube may be left quite free for the full diameter of the objective.

This is perhaps best accomplished by the prism and its fittings being in a separate nose-piece, attached to the tube by a well-made

bayonet catch, when it can be detached as required. By screwing into the broad-gauge thread, after the binocular fitting is removed, an adapter with Society screw, objectives of wide angle, but not requiring the broad screw, can also be used without their being handicapped by the fitting.

This plan, by which there are in fact three distinct arrangements —1st, the broad-gauge screw; 2nd, the Society screw without the binocular; and 3rd, the Society screw with the binocular—is the one adopted by Messrs. Sidle in the " Acme No. 2 " Microscope.*

Homogeneous and Water-immersion Objectives.† — " Akakia," replying to an inquiry whether homogeneous-immersion objectives are to be regarded as useful only where apertures greater than the limit for water (1·33 N.A.) are required, says that " experience has demonstrated that all incident pencils from one refracting medium to another of much greater refracting power, beyond the cone 140° in the rarer medium, make unfavourable angles—angles that cannot be effectually dealt with, and this applies the more the greater the difference between the media. For instance, in a strictly dry lens the aperture between the cone 140° in air (·94 N.A.) and 180° (1·0 N.A.) is practically of little use; in a water-immersion lens the cone between 140° in water (1·25 N.A.) and 180° (1·33 N.A.) is likewise of but little service; and equally in a homogeneous-immersion lens the cone between 140° in the immersion fluid (1·43 N.A.) and 180° (1·52 N.A.) is practically useless. Professor Abbe has arrived at the conclusion that the limit of useful aperture is a much lower figure than 1·43 N.A. [Not so. He considers 1·45 the practical limit, *ante*, p. 472— Ed.] With our present means of construction, however, the lenses which exhibit the finest definition with direct oblique illumination that would utilize 1·25 N.A. are not those lenses of precisely 1·25 N.A., but of higher aperture. It would thus appear that in order to get a well-corrected outer zone of 1·25 N.A., the lens must really have a larger aperture to cope successfully with the difficulties of the marginal aberrations. It should be observed that by the homogeneous-immersion formula the higher apertures (say those beyond ·94 N.A.) are more successfully corrected, because the path of the rays is more regular, and can thus be more definitely calculated. This is clearly evidenced by the superiority of definition seen with homogeneous-immersion lenses, when, by the conditions of the object and the illumination, the effective aperture is reduced well within the limits that have already been attained by the water-immersion formula: it is then seen that for all apertures greater than 1·0 N.A. the homogeneous-immersion formula is to be preferred. I believe it is now generally accepted among expert manipulators that the water-immersion formula has seen its best days, and the time is not far distant when it will be entirely superseded."

Collar Correction of Objectives.‡—Prof. A. Y. Moore considers that collar correction has not received the attention which it deserves,

* See also Bulloch's Congress Microscope, this Journal, iii. (1880) p. 1076.
† Engl. Mech., xxxv. (1882) p. 551.
‡ ' The Microscope,' ii. (1882) pp. 8–11.

being overlooked entirely among the younger microscopists. As so little has been written on the subject, he gives "a few simple directions.

Every objective has a certain colour with which it shows best, and there is probably no object better adapted to the purpose of determining this colour than a well-marked *Podura*-scale. . . . . When a good scale is once obtained, great care should be taken to keep it dry, for when wet it is of no use.

Now, by examining this scale with a first-class ¼ or higher power of medium or wide aperture, it will be seen that the 'exclamation marks' are more or less coloured. Pay no attention to this at first, but carefully turn the collar back and forth until the marks appear sharpest and smallest. That will be the point of best correction, and now the colour of the markings should be noticed. Having carefully determined the exact tint of best correction, throw the objective a little out of proper adjustment by turning the collar towards open point or zero. This over-corrects it, and at the same time notice the change in colour. The markings seem to expand, becoming hazy and not at all sharp. Now turn the collar towards closed until the point of best correction is passed: here the same thing is seen in regard to expansion and haziness, but a different tint seems to make its appearance. By attending very closely to this colour (which is the secondary spectrum), the proper correction can easily be made. I can best illustrate this by the following trial :—

I have before me a $\frac{1}{15}$ objective. By trial over a *Podura*-scale I find that when best adjusted the marks appear of a brilliant ruby red (and most of the finest objectives which I have seen show best with this colour); by turning the collar below zero they turn greenish, while, if turned towards closed, they become pink. Hence at the first trial of any such object, should it appear green, the collar should be turned towards closed until the ruby tint appears, and if too pale a red, or pink, the collar should be turned towards zero. By a little practice the microscopist can tell at a glance which way to turn the collar.

There are some objects on which a correction cannot be thus made ; in such cases the coma must serve as a guide. The edge of a red blood-corpuscle will serve as a good test for practice in this way. By carefully moving the collar back and forth until the edge is sharp and clear, it will be seen that a brisk movement of the fine adjustment causes the edge of the corpuscle to expand, both as it goes beyond the focal point and also within the focal point. If the correction has been made exact, this expansion (coma) is equal both ways, but should the greater expansion be when the object is beyond the focal point, the objective is under-corrected, and the collar should be turned towards zero ; but should it be the reverse, that is, the greater expansion within the focal point, the objective is over-corrected, and the collar should be moved towards closed."

The author then refers to the deceptive appearances produced by a want of proper correction, such as lines or network instead of dots and points ; and that with homogeneous-immersion objectives without

correction-collar the draw-tube should be pushed in if the object appears too green, or if too pink drawn out until the ruby tint is obtained, assuming, that is, that the objective corrects in that colour.

In the above note we remark that Professor Moore does not specify whether the $\frac{1}{15}$ objective was dry or immersion. It should also be observed that in testing the colour-corrections of a large-apertured immersion objective on a dry Podura adhering to the cover-glass, it may happen that there is an appreciable film of air between the scale and the surface to which it adheres, in which case the " ruby " tint may be replaced by a deep red colour which cannot be corrected by the adjustment-collar. The objective will then be acting as a badly corrected dry lens. In such a case a scale must be sought that is more closely adherent to the cover-glass.

It is a fact well known to opticians that objectives of large aperture which are very perfectly achromatized do not yield such sharp definition of a dry *Podura*-scale as those in which the outstanding colour-aberration is of a moderate ruby tint. The more closely adherent the scale is to the cover-glass, the less red should be the tint; and if by means of the vertical illuminator or equivalent means a scale is chosen which adheres closely, the ruby tint will be less pronounced, and the definition generally more perfect.

Measuring Thickness of Cover-glass by Correction Collar.[*]— Professor C. K. Wead points out that the thickness of a cover-glass " may be found quite closely by means of an objective with correction. Taking the covers used above [·0058 inch and ·0123 inch], and having focussed on dust or finger marks on the under side, turn the collar till dust on the upper side is in focus; with the thinner glass several trials gave as the reading of the collar $3°·6$, $3°·75$, &c.; working backwards focussing on the top with the collar at $9°·6$ and then on the lower side by the collar the reading was $6°·1$ twice, a change of $3·5$; mean of seven trials gave $3°·56$; similarly with the thicker cover, mean of five trials gave $7°·58$. If we assume the change of the collar to be just proportional to the thickness of the glass, since the thin glass is ·0058 inch we should have $3·56 : 7·58 :: ·0058 :$ thickness of thick cover: solving we find it to be ·01235 inch—a difference of less than $\frac{1}{1000}$ inch from that found by a Brown and Sharpe's gauge—a quantity scarcely measurable with this gauge. If one has, then, a single cover-glass whose thickness is known, by a simple proportion the thickness of any other one can be found in a moment. For this particular lens the reading of a collar multiplied by $1·6$ will give very closely the thickness in thousandths of an inch. Makers might easily furnish for their lenses the constant multiplier to be used as this $1·6$ is; or divide the scale so as to indicate directly the thickness in thousandths of an inch."

Bausch and Lomb Optical Co.'s Glass Stage and Slide-carrier.[†]—This (Fig. 128, see also Fig. 113) is intended as a substitute for the mechanical stage to a certain extent. It consists of a

---

[*] 'The Microscope,' ii. (1882) p. 72.
[†] From the Company's Price List, 7th ed., 1882, p. 5 (1 fig.).

polished plate of glass, incased in a brass ring, which clamps on the circular stage. The slide-carrier, which moves on it, consists of a light metallic plate, and has protruding from its lower surface four small points ; at its two ends are prolongations, which are bent

FIG. 128.
downward and inward, and, acting as springs, press against the lower surface of the glass. As the contact between glass stage and slide-carrier is only in these six points, friction is reduced to a minimum, and the action of the latter, although firm, is smooth and steady. It is claimed that it enables work to be done with far more facility than in the ordinary brass stage, where the entire surface of the slide bears on it, and that it is altogether more agreeable. The slide-carrier is provided at each end with small milled heads for manipulation, and has spring clips and a stop for Maltwood finder.

Thomas' Vivarium.—Mr. C. Thomas has devised a life-slide which is in effect a modification of the Hardy vivarium, enabling it to be readily applied to observations with high powers. With the earlier form, the upper plate is necessarily so thick that it is impossible to use it for the examination of such organisms as the Cilio-flagellata which require the highest powers.

The new vivarium is shown in Fig. 129, with the two principal

FIG. 129.
plates held together by two indiarubber bands, and a segment of another band forming the sides of the cell as in the Hardy vivarium. The speciality of Mr. Thomas' device is the addition of a third plate of *thin glass*, contiguous to the upper plate and of about the same size, the latter being pierced with a central aperture. We thus have a cell the upper side of which is thin enough to allow high powers to work through it. The thin glass is so supported by the upper plate, with which it is in contact over the greater part of its surface, that we have found from experience that there is practically no risk of breaking it in putting the cell together. A piece of very thin glass can be placed inside the cell and kept close up to the front by wedging it with a small piece of rolled or twisted paper.

The upper plate is made shorter than the lower so that there may be no danger of the plates being pressed together unequally and the thin plate crushed when the apparatus is taken up by one end.

Bausch and Lomb Optical Co.'s Immersion Illuminator.[*]—This (Fig. 130) is designed to utilize the full capacity of medium

* The Company's Price List, 7th ed., 1882, p. 32 (2 figs.).

and wide-angled objectives. In general appearance it is like an ordinary objective. It has an internal diaphragm, which is placed directly under the posterior system of lenses, and is entirely contained in the tube comprising the mounting, therefore avoiding any projection, and allowing the light to enter only from below. By revolving the milled ring of the mounting, the diaphragm is made to pass laterally from the centre to the extreme edge of the illuminator, thereby throwing rays of any desired obliquity, between 0 (central illumination) and the extreme possible limit, 1·52 in crown glass. When the diaphragm is at its extreme limit a second slit, at right angles to it, giving the same volume of light, is opened by the further movement of the milled ring, thus utilizing two pencils at right angles. The illumination is said to be amply sufficient with the highest powers, and the fact that it is used with only central illumination of the mirror, will, it is considered, "prove especially valuable to those who do not possess instruments with the modern swinging substage and mirror-bar."

Fig. 130.

Fig. 131.

The illuminator is also said to give excellent results when used as non-immersion. A cap with minute aperture (Fig. 131) to facilitate centering, and an adapter (to receive the optical part without the diaphragms and so to give full aperture) accompany it.
Gundlach's Immersion Condenser.*—E. Gundlach discusses this subject, and expresses the opinion that of all the apparatus for providing oblique illumination for large apertures, the Abbe condenser has apparently been the most efficient, and has been generally adopted as the most suitable illuminator for the widest angled objectives, hence it is advisable to inquire whether this form of condenser is capable of doing all that is demanded of it now, or that will be demanded in the near future; and to this inquiry he has given much special study. As the full advantage of a very wide-angled objective cannot be had unless light can be made to pass through any part of its aperture at will, the Abbe condenser would be the best, if it were possible, practically, to increase its angle to correspond with that of the objective; but it can be shown, Mr. Gundlach considers, that it cannot be so increased, and that it cannot approach within 20° or more of 1·52 N.A., as is now, or soon will be, desirable.

"If the point where the optical axis of the objective cuts the plane of the object be considered the vertex of an angle which has the extended optical axis of the objective for one side, then the other side of the angle extended downward will cut the under side of the slide on which the object is mounted, at a certain distance from the axis, and this distance is proportional to the thickness of the slide. Besides, if the said angle is equal to half the angle of aperture of the objective,

* Amer. Mon. Micr. Journ., iii. (1882) pp. 85-7 (1 fig.).

then this distance is the radius of a circle which the available front of the condenser, or other apparatus, must cover, so that light may enter the objective at the most extreme angle of obliquity. If this distance, which we will call d, be $\frac{3}{16}$ inch, then the available surface of the condenser must be a circle of at least $\frac{3}{8}$ inch in diameter.

" Now, assuming the thickness of the usual object slide to be $\frac{1}{12}$ inch, though this is hardly enough, if the angle of aperture of the objective is given, we may find the distance d, for with the thickness of the slide, $\frac{1}{12}$ inch, as the cosine, the distance d will be the sine of half the angle of aperture of the objective. If the angle of aperture of the objective be 120°, or 1·31 N.A. in crown glass of 1·52 refractive index, then the distance d would be 0·144 inch, which, however, will not introduce any special difficulty in the construction of an Abbe condenser, as the connecting, or front, surface of the condenser need not be larger in diameter than 0·288, or a little over $\frac{1}{4}$ inch. But when we come up to 140° crown-glass angle, or 1·42 N.A., the distance d increases at once to 0·228 inch, and the connecting surface of the condenser must be at least 0·456, or nearly $\frac{1}{2}$ inch in diameter. With so large a front surface, or as it is better expressed, front aperture, the condenser to be fully up to 140° crown glass, will have to be of an equivalent focus of at least $\frac{1}{2}$ inch, which with 140° in crown glass, will make the back-aperture 1·42 inch, or near $1\frac{7}{16}$ inch, and in mounting it will be pretty close work to get this inside the substage tube. But let us go a step further and suppose an objective of a crown-glass angle of 160° or 1·49 N.A., which may be expected before long. This angle will increase the distance d to 0·47 inch, and the diameter of the front aperture of the Abbe condenser must be at least 0·94 or $\frac{15}{16}$ inch. Now, as the increase of the angle of aperture of the condenser from 140° to 160° will considerably lessen its working distance, it will have to be constructed of so much longer equivalent focal distance as to keep the working distance of the slide thickness, of at least $1\frac{1}{3}$ inch focus (sic), and even with this it will be hard to get the required working distance. But a condenser of $1\frac{1}{3}$ inch equivalent focus and 160° crown-glass angle will require a back-aperture of 3·98 inches.

" Attaching this mammoth condenser to a Microscope having a stage, and consequently all the base parts that support it, on the same scale, we should have an instrument of such proportions as would give the appearance of a derrick, rather than that of a Microscope.

" These examples satisfy us that the Abbe condenser, useful as it is, by no means fully meets all the requirements of oblique illumination, and that practically this illumination cannot very well be made of greater angle than it already has. Hence we have either to find some other suitable means of obtaining still more oblique illumination, or to give up, as useless, the increase of the angle of the object for an increase in performance.

" So it is wise to consider the solution of this problem of illumination before the further improvement of the objective by the increase of angle. In this direction, I desire to submit for consideration the idea of an oblique light reflector represented in Fig. 132. S represents the

object-slide; R the proposed reflector. It is a section of a sphere. The upper plane surface is to be brought in contact with the slide by means of a suitable fluid in the usual way. The under surface is concave. The dotted lines show the direction of the light, which

Fig. 132.

undergoes an inner total reflection at the surface C. Perhaps this reflector will answer for the next limited period; and when even this shall prove to be insufficient, I propose to mount the object on the plane surface of this reflector. In this way the theoretical limit would be reached, and opticians can go on constructing objectives that will take and utilize the oblique light of this reflector."

[It is unnecessary to provide for any apertures in excess of $1·45$; and the assumption of $\frac{1}{12}$ inch for the thickness of the object-slide is unnecessarily large, $\frac{1}{16}$ inch being the average. With these alterations the maximum figures given by Mr. Gundlach ($1\frac{5}{16}$ inch for the front lens and $3·98$ inch for the back lens) would be reduced.—Ed.]

Symmetrical Illumination.*—Mr. Gundlach also desires " to call attention to another idea, which, if carried out properly, may be of advantage. I thought that a good result would be obtained if the object should be obliquely illuminated symmetrically, i. e. from diametrically opposite sides at the same time, with equal obliquity, intensity, and quantity, rather than from one side only; for the secondary spectrum, with the unavoidable slight chromatic over-correction of the outer part of the objective, produces a more or less visible and disturbing spectrum, which will be neutralized in the proposed way. I have tried this, and after some difficulty I think I succeeded in obtaining a result in resolving which I could not get in the usual way. From my limited experience in this matter I can say, however, that this symmetrical illumination requires a very delicate fine adjustment; the one I used gives a motion of only $\frac{1}{360}$ of an inch at a full turn of the screw; for apparently the two images, projected separately by the illumination from each side, do not move in the direction of the optical axis when the screw is turned, but they move each toward the side from which they are projected, and it requires great precision to get them to coincide perfectly. Further desirable experimenting in this, for which I do not deem myself competent, I feel obliged to leave to experienced and skilful microscopists, and I

* Amer. Mon. Micr. Journ., iii. (1882) p. 88.

shall be grateful if informed of the results of any experiments tried by them."

Gundlach's Substage Refractor.[*]—This apparatus, intended for measuring the aperture angle of wide-angled objectives, consists of a small crown-glass cube, with sides about $\frac{3}{16}$ inch. One face is opaque, the one opposite and the two others opposite each other, polished. The cube is made to adhere, by means of a suitable homogeneous medium, to the front surface of the objective by the polished surface opposite the opaque side. Then a ray of light must enter each of the polished side surfaces in the plane described by the optical axis of the objective and a line perpendicular to those polished surfaces, and at such angular inclination to the optical axis that it will pass through the objective close at the edge of its aperture, and emerge from it in the direction of the optical axis.

The angle described by the refracted rays inside the crown-glass cube, is equal to the crown-glass aperture angle of the objective, and is :—

$$\cos n = \cos \frac{a}{r},$$

a being half the angle described by the two rays before entering the cube, r the refractive index of the crown glass, and n the crown-glass angle of the objective.

Silvered Convex Lenses v. Concave Mirrors.[†]—Mr. C. V. Boys points out that convex lenses silvered at the back make excellent and easily-constructed concave mirrors. Since both surfaces conduce to bring the light to a focus flatter curves may be used than are necessary for a plain concave reflector of the same focal length ; also since the two surfaces are not parallel false images are not produced, so that the advantage of glass silvered at the back remains without the usual disadvantage.

Binocular Vision in the Microscope.[‡]—Professor C. Cramer, in connection with a description of Prazmowski's binocular eye-piece, discusses the conditions of stereoscopic binocular vision in the Microscope. In particular he points out the error of the views of Nägeli and Schwendener that the depth of the field of view is of only secondary importance to the stereoscopic effect, a view which they attempt to support by the fact that in the ordinary stereoscope the two pictures are perfectly plane, but yet produce the impression of solidity. These pictures require, however, to be taken from different points of view, or no stereoscopic effect whatever will be produced. Microphotographs of statuary, &c., do not appear to be more solid when observed with a stereoscopic Binocular than with a single eye. The author further describes the appearances, by the left- and right-hand halves of an objective respectively, of oil-globules and air-bubbles in water by transmitted light and a small cylindrical opaque object, as establishing to what in fact the stereoscopic effect is due. He also

discusses the effect of observing the two different images with a single eye (when each point of the object is seen in one direction only), and the difficulties attending the recognition of the respective distances of parts of an object with one eye. With *true* solid vision with two eyes they must constantly be accommodated according as we desire to see the nearer, central, or more remote parts of the object. With *apparent* stereoscopic vision this is not, however, necessary.

Finally, the author expresses his opinion as to the value of binoculars as follows :—" For the solution of natural problems the author cannot expect much of the stereoscopic Microscope since the sharpness of the image leaves much to be desired.[*] Its use for instruction is, moreover, rendered very difficult in that each observer must regulate not only the focus but also the lateral distance of the eye-pieces. Nevertheless, for microscopical objects of complicated form the instrument may here and there prove useful."

Miniatured Images.—In the President's Address (*ante*, p. 158) a brief reference is made to the unsatisfactory character of experiments made on miniatured images—spider-lines, for instance, " miniatured to the fourteenth part of the hundred-thousandth of an inch." The illusory character of all conclusions on the subject of microscopical vision, which are based on the observation of miniatured images, is demonstrated by the following discussion, which we extract from some notes on the subject by Professor Abbe.

FIG. 133.
Let O (Fig. 133) be an object—a grating or wire gauze, or spider-line, Q its miniature image, projected by means of an objective S, Σ the objective of the Microscope by which this miniature image is observed, and P the re-enlarged image which is finally seen through the eye-piece. The linear aperture of the objective Σ may be denoted by a; the corresponding aperture-angle by ω; the angle of convergence of the delineating pencils at the image P by v; the angle of divergence of the pencils admitted from O by u; the distance of O from S by d, and the distance of the final image from Σ by δ (these distances being measured from the posterior principal foci of the two objectives which will practically be very near to the back lenses), and f and ϕ the equivalent focal lengths of S and Σ respectively. All the conditions of the observation are now strictly defined.

* In the particular case, on account of the interposition of the prism and additional eye-piece combination.

Now what is claimed is, that if the spider-line at O is $\frac{1}{10000}$ inch in breadth, and the objective S diminishes by 100 diameters, we should have at Q a miniature image of $\frac{1}{1000000}$ inch, and that this is depicted by the objective Σ.

This is, however, pure hypothesis, without a shadow of proof that the observation of miniatured images is the same thing as that of real minute objects.* The only *fact* is, that the observer sees the object O as it is delineated by the *composite objective* S + Σ at P.

For demonstrating the fallacy involved in the assumptions in question it is not necessary to concern ourselves with any theory of microscopical vision—it is sufficient to rely on the ordinary principles of geometrical optics.†

In the first place it is readily shown that the appearance of the supposed miniature—as it is actually seen through the Microscope— has no essential connection with that miniature, the image at P, which is actually and only seen, not even requiring the existence of any miniature, so that the conditions of visibility of things are discussed which need not even exist at all.

Suppose the objective S under-corrected and Σ over-corrected in a corresponding degree—the aberrations of both systems just balancing one another—the object at O will be visible at P with the same distinctness as if S and Σ were strictly corrected ; for the total system (S + Σ) is so corrected. Now it is obvious that under the above assumption (antagonistic correction-defects in the two systems) no image of very minute dimensions can be depicted at Q at all, where we should only have large circles of confusion.

It need hardly be said that it is an obvious fallacy to infer anything concerning the existence or operation of a given phenomenon from observations which would not be altered in the least degree if that phenomenon did not exist at all.

The true signification of the observations in question is obtained by determining the optical character of the composite system (S + Σ). This can be done by the following formulæ, which give respectively (*a*) the focal length, (*b*) the amplification, and (*c*) the aperture angle, by which three things the action of every optical system is perfectly determined. If two systems are identical in all these respects (and

---

* Whether a real (isolated) object, such as a fine line (bright or dark) of $\frac{1}{1000000}$ inch is visible or not visible through a given objective is only a question of light, of sensitiveness of the observer's retina, and of good correction of the objective, just as in telescopic vision a single star is always visible, however small its visual angle, provided it is sufficiently bright, but a double star requires a certain minimum aperture of the telescope depending on the angular distance apart of the stars.

† On the principles of the Abbe theory of microscopical vision the matter would stand thus :—If there were at O a coarse object of say $\frac{1}{10}$ inch in diameter, the miniature image would in fact be approximately the $\frac{1}{10}$ part in diameter, i. e. $\frac{1}{100}$ inch. But this is not the case with objects and images of such minute dimensions as above referred to, the miniature of the spider-line, if it could for instance be photographed (the system S being absolutely free from aberrations) would be found to be a rather broad band not less in diameter than half the wave-length of light.

equally well corrected) they must always give the same image of the same object. With the notation indicated above, the equivalent focal length F of the total system (S + Σ) is

$$\frac{1}{F} = \frac{f}{\phi} \cdot \frac{1}{d} + \frac{\phi}{f} \cdot \frac{1}{\delta},$$

the linear amplification N (of the ultimate image at P),

$$N = \frac{\delta}{d} \cdot \left(\frac{f}{\phi}\right),$$

and the aperture angle u of the total system (resulting from the linear aperture a of the objective Σ),

$$u = \frac{\delta}{d} \cdot \frac{f}{\phi} \cdot v \quad \left(\text{where } v = \frac{a}{\delta}\right);$$

therefore

$$u = \frac{a}{d} \cdot \frac{f}{\phi}.$$

To take an example : let S be an $\frac{1}{8}$ inch and Σ a $\frac{1}{12}$ objective, $d = 400$ mm., $\delta = 200$ mm., $a = 3$ mm., $f = 3$ mm., $\phi = 2$ mm.—then we have

$$\frac{1}{F} = \frac{300}{200} \cdot \frac{1}{400} + \frac{200}{300} \cdot \frac{1}{200} = \frac{3}{800} + \frac{1}{300} = \frac{17}{2400}$$

$$F = \frac{2400}{17} = 141 \text{ mm. } (= 5\frac{1}{2} \text{ inches approximately})$$

$$N = \frac{200}{400} \cdot \frac{300}{200} = \frac{3}{4} \ .$$

The ultimate image at P is therefore a slightly (3 : 4) diminished image of O.

$$u = \frac{3}{400} \cdot \frac{300}{200} = \frac{9}{880}$$

which is an aperture angle of about $\frac{2}{3}°$.

Thus the simple *matter of fact* is that if the miniature of O is observed at P we observe the *real object* O by means of a very *low-power* objective ($5\frac{1}{2}$ inches) of *very low* aperture ($\frac{2}{3}°$) under a very low linear amplification, and nothing more is shown therefore by the observation but this, that spider-lines and similar things can be seen through very low-power objectives, which nobody will doubt.

The formulæ for F, N, and u show that the focal length of the actually effective system, the ultimate amplification, and the aperture angle do not depend on any other elements except (1) the distances d and δ of the object and the ultimate image, (2) the ratio of the focal lengths of the objectives S and Σ, and the latter in addition (3) on the linear aperture of the objective. Now F, N, and u, as has been said, comprise *all* elements of the effective system (S + Σ) which can possibly have any influence on its performance (spherical correction of

the total system being supposed), and the same values of F, N, and u will therefore indicate the same effect always. Consequently we shall obtain exactly the same results whether we apply an $\frac{1}{8}$-inch and $\frac{1}{12}$-inch, or instead of these any two *low*-power objectives with the same *ratio* of the powers (2 : 3), for instance a 2-inch and a 3-inch or (the simplest case) a single lens of $5\frac{1}{2}$ inches, always preserving the distances $d = 400$, $\delta = 200$ and the narrow diaphragm corresponding to the linear aperture of the $\frac{1}{12}$ (3 mm.).

These considerations show the illusory character of the experiments in question as all the observations would have had the same result even if objectives had been applied not of the high powers actually used but of low power or even consisting of a single lens, that is under circumstances in which either no miniature at all is formed, or none of the minute dimensions claimed. Nothing can be inferred from such experiments in regard to *high-power* vision, at any rate. They are in fact, experiments on *low-power* vision, and under artificially and unnecessarily *complicated* conditions, a complicated system, $E + \Sigma$, composed of a number of lenses being employed for obtaining no other effects than can be produced by a single lens of small aperture.

Black Annuli and Lines of Spherules and Threads.—In the same Address * is a reference to the attempts made to demonstrate the defective vision of objects under objectives with wide apertures, by means of glass spherules and threads, the characteristic black lines seen when low apertures are used nearly disappearing when the aperture is increased.

It is true that transparent spherules and threads of $0\cdot1$ inch in diameter, or many times greater than a wave-length, behave according to the laws of refraction, and show annuli, &c., which are very strong and black with low apertures, but are much less marked with wide ones, but very minute spherules or filaments of the same shape, which are only a wave-length or less in diameter, do not show the black annuli and lines *even with the narrowest apertures*. They appear either uniformly illuminated or with a gradation of light which has not the least similarity to the annuli, &c., of the coarser refracting spheres or cylinders, and this for the reason that such minute objects do not act as *refracting* bodies but only by the retardation of the transmitted waves.

This shows the essential fallacy involved in the experiments in question. That the black annuli of the coarse objects become indistinct with wide apertures proves only that wide apertures are not the proper means for examining such coarse objects. This, however, requires no proof nowadays, when it is well recognized that wide apertures should not be applied for objects which are completely depicted by low ones.

The notion that minute objects which require high powers in order to be seen are better seen with low apertures, is a conclusion derived not from direct observation, but simply *inferred* from the *supposed*

* pp. 158–9.

analogy of the phenomena presented by large objects, and with the assumption that the same phenomena must hold good in the other case also.*

Curiosities of Microscopical Literature.—One would hardly have expected to find such a paragraph as the following in a book published in London in 1881, even although written " without assuming the possession on the part of the reader of other attainments than those possessed by the average schoolboy or schoolgirl " :—" In the " same year (1824) Tulley, of London, succeeded in constructing for " the first time in England an object-glass of 3 lenses. Sir John " Herschel, Professor Airy, and Professor Barlow [no mention of " Lister !] furnished valuable contributions to the theory of the " achromatic object-glass. More recently a suggestion of Sir David " Brewster's has been carried out, by the construction of lenses of " diamond. By these and other modern improvements, especially in " the mode of illuminating the objects, investigations are now carried " into structures so minute that magnifying powers of 2000 or 3000 " diameters have to be used " ! †

The suggestion of diamond lenses was *abandoned* more than fifty years ago,‡ and none of the present generation of Microscopists have ever had an opportunity of testing the " improvement " which it is suggested the diamond has been to microscopical investigation.

When will popular writers get to understand that neither the size nor the magnifying power of a Microscope forms the standard of its efficiency, and that amplifications of 2000 or 3000 diameters could be obtained without any difficulty half a century ago, when, notwithstanding, much less was visible than can now be seen with a tenth of the power.

In a subsequent paragraph it is stated that the " binocular form of construction, though attempted very long ago, was not successfully carried out till 1851."

* It must also be borne in mind that it is impossible to make reliable observations as to the relative performance of objectives with different apertures, unless the fact of their perfect correction is ascertained *independently of the observations in question,* that is on objects the correct appearance of which is not dubious or hypothetical, as for instance, the outlines of thin silver films.

Again, it is out of the question in *such* observations to make arbitrary changes in the conditions under which the objective acts, as shortening and lengthening the tube, interposing other lenses between the objective and the eyepiece, using the objective with immersion fluids for which it was not constructed, &c.

As wide apertures allow of much greater aberration than low ones, it may happen that the former, if the correction is not very carefully made, will show less than a low aperture, even if this is also badly corrected, because the relative deterioration of the image is not so great.

† ' A Popular History of Science,' by R. Routledge (8vo, London, 1881) p. 515.

‡ Dr. Goring suggested diamond lenses to A. Pritchard in 1824, and he made one in the same year (see Sir D. Brewster's ' Treatise on the Microscope,' 1837, pp. 13–21). Sir D. Brewster's reference to diamond lenses will be found in ' Treatise on New Philosophical Instruments,' 1813, pp. 402–10 ; and ' Treatise on Optical Instruments,' 1832, p. 39.

[Several corrections necessary. (1) Baker (and not Trembley) is credited
with the first demonstration of the vitality of *Hydra* when cut to pieces,
while (2) the discovery of achromatism and the manufacture of
achromatic lenses and the revolution which they caused in Microscopy
has been lost sight of, the position of the Microscope in 1830 being thus
dealt with :—" About 1830 the mechanism and general arrangements of
the materials employed began to show a great advance upon the
older instruments, but it was in the lenses that the chief improvements
were manifest, and principally in the higher powers. The lower powers,
composed of a single lens, remained much as before, while the
improvements in the higher powers were carried on to a wonderful state
of perfection. The provoking refraction which interfered with the
definition of an object when seen with a high power is now got rid
of, and what was obscure and doubtful before is no longer so, but
becomes a matter of demonstration."]

β. Collecting, Mounting and Examining Objects, &c.

Preservative Fluids for Animal and Vegetable Tissues, and Methods of Preservation.*—Many years ago, Professor F. Pacini commenced to make microscopical preparations with a view of preserving types of different elements of tissues, both normal and pathological, and experimented largely with aqueous solutions of different substances in variable proportions; then, having put up a large number of preparations in these solutions, he allowed some years to elapse in order to see which had best resisted the effects of time. Many, of course, perished; but those which are preserved serve to indicate the best methods to employ.

Professor Pacini does not deal with the well-known methods of preserving, by means of Canada balsam or glycerine, microscopical preparations of hard, dry, or indurated parts, merely observing that tissues, when they have been dried or indurated to obtain sections, have lost their water of organisation, and are not suited to give an exact idea of their minute structure; it is necessary that they should be preserved in an aqueous medium of low density, in order that they may present as natural an aspect as possible. Very thin sections of tissues, when preserved in so dense a medium as Canada balsam or glycerine, become transparent; it is then necessary to stain them in order to render them visible, and whilst they are then certainly more pretty to look at, they are not natural.

* Journ. de Microgr., iv. (1880) pp. 136, 191, and 235.

The fluids themselves, whose use the author describes, are already known; the new matter in his present communication is the account of the modes in which he finds they can be most advantageously used.

Bichloride of mercury, or corrosive sublimate, is the principal basis of the solutions. Combining with the histological elements, both animal and vegetable, it renders them insoluble, so that they can be preserved indefinitely in an aqueous medium. But, as the bichloride of mercury coagulates and precipitates the albuminous matter that exists in the interstitial fluids of the tissues, to prevent this coagulation salt is associated with it for certain preparations, and acetic acid for others, and in more or less considerable quantities, according to the effects to be obtained.

		Parts.
I. Bichloride of mercury		1
Distilled water		200
II. Bichloride of mercury		1
Common salt		2
Distilled water		200
III. Bichloride of mercury		1
Common salt		4
Distilled water		200
IV. Bichloride of mercury		1
Acetic acid		2
Distilled water		300

No. I. is of limited use, but will preserve indefinitely all histological substances, both animal and vegetable, which are solid and non-albuminous, for hollow substances either swell or become too opaque by the coagulation of the albumen. It can, however, generally be substituted for the other solutions when it is desirable to entirely remove the salt or acetic acid from the solution in which any given preparation has been placed.

No. II. may be generally employed for all tissues both cellular and fibrous, animal or vegetable, provided they are sufficiently dissociated in sections of extreme thinness, because they become somewhat opaque, regaining, however, in time a certain transparency. It is especially useful for the blood-corpuscles of cold-blooded animals having a less density than III.

No. III. serves specially for the blood-corpuscles of warm-blooded animals.

No. IV. serves best for the nuclei of animal tissues, but it swells up the fibres and distorts the forms of the cells. Still, in certain cases it is very useful, and it preserves the white blood-corpuscles admirably.

All the solutions should be employed in sufficiently large quantities, and the specimen kept in it for 4–5 days or longer, in order that it may have time to take up a sufficient quantity of the bichloride of mercury before being finally closed up.

The use of metallic instruments is to be avoided, because, being attacked by the bichloride of mercury, they give rise to cloudy precipitates, which render the prepared objects thick. Sections should be cut before plunging them in the solution, and when it is necessary to tease out the elements of a tissue it should be done with porcupine quills or pointed goose-quills.

If it is wished to preserve red blood-corpuscles, the blood must be diluted with at least 50 to 100 times its volume of solution II. (or No. III., see above); this is decanted after the lapse of 24 hours, and changed in the same way three or four times. White blood-corpuscles may be isolated by destroying the red ones; this end is attained by the use of solution IV., by means of the acetic acid contained in it. It must be applied for 48 hours in the proportion of from 50 to 100 times the volume of the blood, and must, as in the former case, be changed three or four times. If transferred to solution II., the leucocytes gradually regain their original form. Spermatic fluid is preserved in solution II. The liquid must first be stirred round with a glass rod to prevent the elements adhering.

Epithelia are examined in the same solution after the parts which support them have remained some days in the solution, spread out, if necessary, on sheets of guttapercha with cactus thorns.

Blood-vessels may be beautifully injected naturally by putting the tissues which contain them into solution II. or III. for a considerable time (fœtus eyes intended to show the vessels of the pupillar membrane should be treated thus for 20 days). Nerve-fibres may be studied advantageously in the cranial and intra-ocular nerves with their comparatively thin medullary sheaths. Muscular fibres are best examined in the muscles of *Petromyzon* after a treatment of several days with solution II.

If it is desired to collect Infusoria or other very small organisms, animal or vegetable, particularly when they are in movement and scattered through a large quantity of water, a tolerably large glass vessel (in order to collect a sufficient quantity) should be filled with the water, and a little of the solution No. II. added. All the Infusoria being killed by the bichloride of mercury, they fall slowly (in three or four days) to the bottom of the vessel, the more slowly as they are smaller. The greater part of the liquid is then to be decanted by a siphon and replaced by some of the solution, which should be changed three or four times. The Infusoria can then be preserved in a bottle or mounted.

Preparing Sections of Axis-cylinder. — For extensive lengths of axis-cylinder G. Bufelius [*] proceeds as follows :—Fragments of nerves of the dog or rabbit are laid for 24 hours in Müller's fluid. They are then transferred to an aqueous solution of corrosive sublimate ($\cdot 5$ per cent.) in which they remain several days, the liquid being constantly changed, until the solution undergoes no further alteration. The tissue is then teased and treated with dilute picro-

* 'Lo Sperimentale,' 1880, Nov. Cf. Jahresber. Virchow and Hirsch for 1880, p. 22.

carmine. Finally 33 per cent. alcohol, and then absolute alcohol, are applied, and the specimens mounted in dammar.

Mounting Gizzards of Insects.*—Dr. T. J. Sturt was formerly content to pull off the head of a cricket, drag with it the stomach, and attached to it the gizzard or organ containing the pyloric teeth, skin off the muscular coat with the thumbnail, cut off any portion of intestine, and then mount.

This plan, however, missed many interesting points in the stomach and gullet, and he now prefers to kill with a drop of benzine, cut off the extreme tail, pull off the head, cut off the whole intestine, and put it in a 1 oz. phial with 5 or 10 drops of liquid potash. After it has stood about half-an-hour, partly fill with water and shake it well to detach the muscular coat and tracheæ; then slit it up, wash and adjust on a slide. Drain away any moisture, apply a drop of carbolic acid, and place on the thin glass. After a few minutes this will absorb all moisture, and render it quite transparent. If it does not, put a drop of acid at the edge and tilt the slide to drive off the first acid; then put a little balsam on the edge, tilt the slide, warming it to render the balsam more limpid, and it will gradually take the place of the acid, the lines of demarcation between the two being distinctly visible.

Preparing Tape-worms.†—Dr. G. Riehm recommends the following treatment of specimens.

To prevent contraction at death, he cleans the living cestode with a brush, and holds it in the hand until it has extended itself under the action of the warmth, and then rolls it upon a glass tube and plunges the whole into spirit; undue adhesion to the glass is remedied by soaking in water. Such specimens are well adapted for mounting under pressure; they may be stained with alum-carmine or with hæmatoxylin; if with the latter, the specimen should be treated with acetic acid for a minute after staining and then washed in ammonia to remove excess of colour.

For minute investigation, sections made parallel to the flat surfaces are preferable. To prevent the last sections breaking out of the imbedding mass, this should be made of equal parts of paraffin and white wax with the addition of one or two drops of Canada balsam dissolved in turpentine for each gramme of the mixture. The razor should be wetted with benzine, care being taken not to moisten the object itself too much with the benzine. To secure having the sections cut in the right place, the specimen is soaked in turpentine, placed in a watch-glass of imbedding mass kept liquid by heat, and left there until seen by its transparency to be thoroughly penetrated; some of the mass is then removed with a hot instrument and placed on a slide and pressed out, the specimen is placed on the stage of the microtome and the slide with its paraffin is placed on it; when cool the slide may be removed, leaving the specimen imbedded in a strictly horizontal position. The excretory vessels are injected with

* Engl. Mech., xxxv. (1882) p. 282.
† Zeitschr. Ges. Naturwiss., vi. (1881) pp. 547–51.

Berlin blue by simple insertion of the syringe; if the animal is moving actively the injection runs forward with difficulty and in any case the neck and head require manipulating with the finger or a wet brush, in order to drive the injection through the narrow portions of the vessels which occur at the joints.

Staining and Preserving Tube-casts.[*]—To stain and preserve tube-casts, A. T. Parker finds a logwood solution better than any other, made by adding five grammes of the extract of logwood, and the same quantity of alum, to 100 ccm. of water. The extract and alum should be thoroughly triturated before the water is added, and the whole then left until the extract is completely taken up by the water, which requires several hours, and then filtered. The best course to pursue in staining is to shake the bottle containing the urine, then pour it into a conical flask; after several hours, when the deposit is complete, either draw or pour off the supernatant fluid, and add to the deposit about an equal quantity of the staining fluid. At the end of one or two days, the casts will be stained a beautiful reddish-purple.

Casts prepared in this manner over nine months since, though left in the tube in which they were stained, are as perfect as at the time they were prepared. After staining, the casts can be mounted in balsam or dammar without undergoing any change.

Method for Dry Preparations.[†]—Dr. G. Riehm, after stating that the method of making the dry preparations recently shown has not been published by its original inventor, describes what he terms a simple and inexpensive process for attaining the same end.

After being arranged so as to show the required anatomical points, the specimen is hardened, preferably by chromic acid (Mollusca), Müller's fluid, picrosulphuric acid or (when the tendency to shrinking is not great) in alcohol. All water must then be extracted with absolute alcohol; if this is not thoroughly done, shrinkage occurs later. It is then placed in oil of lavender or oil of turpentine (the latter is, however, sensitive to traces of water), and, when quite saturated, extended with pins or otherwise on filter paper and left there for forty-eight hours. The specimen has then a brilliant white colour and maintains its colour and condition if protected from dust. The principle of the method consists in the prevention of decomposition by removal of the water and the protection of every particle from the action of the aqueous vapour and oxygen of the air by an investing film of resinous matter, the result of oxidation of the turpentine or oil of lavender. The cost of preparing such an object as the frog's intestine is about 30 pfennings (3½ pence, English value), and may be reduced by distilling the oil and using it again, and by employing the old absolute alcohol for approximate dehydration of other specimens, an important recommendation in the case of museums and other institutions. A dealer in Halle, named Schlüter, undertakes to supply specimens of the more

---

* Amer. Mon. Micr. Journ., iii. (1882) pp. 153-4.
† Zool. Anzeig., ix. (1881) pp. 672-3.

ordinary objects, prepared in this way. By comparing this process with that described at p. 706 of vol. i. (1881) of this Journal, it be seen that Dr. Riehm's is essentially the same as that of Prof. C. Semper. This gentleman asserts * his claim to the credit of having first made it public, and mentions three other scientific men who have published similar accounts. He disputes Dr. Riehm's explanation of the action of the turpentine, stating that the preparations are readily softened by water. The expense, also, in time and material is not small. Although the white colour seems to be an advantage, it may sometimes be necessary to restore as nearly as possible the colours of life, and this may be done by immersion in a mixture of glycerine and solution of sugar, and then drying; or the white objects may be painted either with honey or oil colours.

Preserving Infusoria. †—E. Maupas, referring to M. Certes' view that the exposure of the Infusoria to the action of the vapour of osmic acid should last from 10 to 30 minutes, says that this time appears to him much too long. He obtains a result much more rapid in the following way. Deposit the drop of water containing the Infusoria so that it shall spread as little as possible on the slide, and then invert it over the neck of the bottle containing the osmic acid (1 per cent.) having an opening sufficiently large so that the drop shall not touch the sides. By this plan the Infusoria never resist more than half a minute.

Mounting Mosses and Hepaticæ. ‡ — M. Delogne recommends glycerine-gelatine which is specially valuable for the study of the stipules of the Hepaticæ, organs which are ordinarily very difficult to see. A special advantage is that it renders a cell unnecessary.

Preparing Bacteria of Tuberculosis.§—Dr. E. Van Ermengem, referring to Ehrlich's improvement of Koch's method,|| describes some modifications of his own which makes it absolutely sure in its results.

Instead of making a solution of the aniline in water, which only takes up 1 part in 30, an alcoholic solution is made, 4 grammes of liquid aniline in 20 grammes of alcohol at 40°, adding an equal quantity of distilled water, and filtering before use. The most stable coloring agents the author finds to be sulphate of rosaniline and methyl-violet B B B B B. The preparations, after having been decolorized by dilute nitric acid, are well washed in distilled water.

Baumgarten also recommends ¶ the following as more simple and expeditious than any others. After having spread the tuberculous matter on the cover-glass, it is placed in a watch-glass and covered with distilled water, to which is added some drops of a 33 per cent.

solution of caustic potash. Without any further preparation the bacteria may then be recognized under a power of 400–500, particularly if a light pressure is applied to the cover-glass so as to disengage the bacteria more completely from the detritus which surrounds them. To distinguish them more clearly from the other bacteria, the cover-glass may be dried by passing it rapidly two or three times through a flame and then staining by a concentrated aqueous solution of aniline violet or other colour. The bacteria of tuberculosis are *absolutely colourless*, while the other bacteria, micrococci, &c., are plainly coloured. The whole process only takes ten minutes.

Preparing Diatoms.*—Dr. R. S. Warren gives detailed directions for the preparation of diatoms, especially for separating them from sand and broken species, the directions for which hitherto published he thinks are insufficient. Coarse sand may be got rid of by repeated settlings and decantations, but it is different with the fine sand. Graduated settlings and decantations have been advised, but these are insufficient, as despite all care, more or less of light silt will float with the light forms of diatoms, and the heavy forms will fall to the bottom with the heavy sand. Whirling in an evaporating dish has been advised, but this is insufficient, and Dr. Warren has found no method better than the one he has used for several years, and which he has never seen described or hinted at except in regard to whirling.†

"If the material contains the lighter forms only, I first use whirling force as follows:—I take an evaporating dish of a size according to the quantity of material, and fasten it on the wheel of my turntable by means of a narrow rubber band passed over it and under the wheel. The material is diffused in five or six times its bulk of water. An empty wide-mouth bottle is near the turntable, and should have the capacity of two or three times the quantity of diffused material. Shaking the material well, I fill the evaporating dish about two-thirds, and then whirl it with considerable rapidity till I think the sand has mostly settled at the bottom of the dish, for the whirling motion causes it to fall. I then pour off the unsettled portion into the empty bottle, and add more of the material to the sand and diatoms remaining in the dish, and stir with a narrow strip of glass; the whirling is repeated; and so on with all the material. When this has been done, water is added to the portion in the dish, and the process continued till no diatoms remain in the sand. To ascertain this, the dipping-tube again comes into use. The material is treated in this way several times, till no sand can be obtained by it. If the material contains heavy diatoms like the large *Pinnulariæ*, *Triceratium favus*, and heavy disk-forms, the whirling process cannot well be used, for these heavy forms fall to the bottom of the dish with the sand.

"After the above process is ended, I proceed as follows, and this is,

---

* Amer. Mon. Micr. Journ., iii. (1882) pp. 111–5.

† Mr. F. Kitton subsequently (op. cit. p. 153) refers to his own papers in 'Science-Gossip,' 1877, pp. 145 and 217, as containing all or nearly all Dr. Warren's methods.

in most cases, the only method used after the boiling and washings. I have a slide of polished glass $3\frac{1}{2}$ inches by $4\frac{1}{2}$ inches; a smooth block of wood 4 inches by 5 or 6 inches, and 3 inches thick; two wide-mouth bottles of 4 to 6 ounces capacity, with thin, projecting lips, one empty, the other filled with the material thinly diffused in water; several pieces of considerable size of old worn cotton-cloth, and, for I like it best, a clean linen pocket-handkerchief, and a small table. The table I place beside my wash-bowl, which is supplied with water—not filtered in this instance—through a pipe and faucet, and on it are arranged my bottles, block, and cloths. I place the glass slide on the block, taking care that the latter is level, and, well shaking the material, pour a little of it on the slide, and then quickly pour it off, tipping the slide so that the material will flow off from a corner of it into the empty bottle. The diatoms float off into the bottle, and the sand adheres to the slide. The slide is then washed by letting water upon it from the faucet, then wiped as well as may be with one of the large pieces of cloth, and then the surface to be used is wiped with the linen handkerchief. This last wiping dries the surface thoroughly, and removes any little shreds of cotton which may have adhered to it from the cloth. Care is taken that none adhere. In this way the material is all worked over, and this treatment has to be repeated perhaps many times before the material is sufficiently rid of the sand. It may be that before this is accomplished, the sand and diatoms will cling together on the slide, causing considerable loss of the latter. This is owing to little particles of matter getting into the material from the cloths, or from the air, and cannot be prevented. As soon as this clinging is detected, which is easily done by occasionally examining the slide under the Microscope, first drying it after pouring off the material, the latter should be boiled for a minute in sulphuric acid, to which is added a little chlorate of potash while boiling. Of course the diffused material is poured into a beaker, allowed to settle, and the water drained off. It is then washed and the treatment continued. When the material is at last freed of sand, it is boiled a last time in sulphuric acid, chlorate of potash being used as before. It is then thoroughly washed and properly diffused in dilute alcohol for mounting. The alcohol should be filtered as well as the water.

" In this last process some of the diatoms will adhere to the slide, but this is of little consequence if there be plenty of material. As the cloths get pretty wet, as they will, they should be exchanged for dry ones."

Modification of Paraffin-imbedding.[*]—The ordinary method of imbedding delicate objects in paraffin is attended with so many objections, such as the disagreeable shrinking, brittleness, and fragility which the object shows by lying long in oil of turpentine or in a warm solution of paraffin in oil of turpentine, that O. Bütschli endeavoured for some time to find a substitute for the latter. After several experiments he found chloroform to be a very excellent sub-

* Biol. Centralbl., i. (1881) pp. 591-2.

stitute, and has used it for some time with most satisfactory results. The following is the method employed in the preparation of very delicate objects.

After having removed the water from the object in the usual manner by alcohol, it must be laid for a short time in pure chloroform, until it is completely saturated. The object is then placed in a solution of paraffin in chloroform which is so made that it is fluid at a temperature of 30–49° C., but firm at a moderate temperature. To retain it in a fluid state while the object is in it, it is sufficient to place it in lukewarm water. The author prefers a solution of paraffin in chloroform saturated at 35° C. In this the object is placed until it is thoroughly impregnated with the solution, for which $\frac{1}{2}$–1 hour is sufficient. The object is now placed in a watch-glass with a little of the solution, and the chloroform is completely evaporated at a very moderate temperature (40–50° C.), which is sometimes a long process as the chloroform escapes very slowly when mixed with paraffin. Larger objects can be transferred direct from the solution into melted paraffin in the same way as in using the mixture of paraffin and oil of turpentine. For delicate objects which must be completely and uniformly saturated with paraffin, the first method is in any case more to be recommended. Complete evaporation of the chloroform is also a necessity, for the presence of even a small quantity is apt to make the paraffin very soft. To make the sections the object can either be poured with the melted paraffin upon a small piece of paraffin, or after it has been placed in a larger mass of melted paraffin, it can be poured into a paper box in the usual manner.

This mode of imbedding is the most harmless and effective which the author has hitherto employed. Both object and paraffin form a thoroughly compact mass, which can be cut exceedingly uniformly. The paraffin which remains after the evaporation of the chloroform is of a very uniform structure without any tendency to crystallization, which very much favours the making of thin sections. With careful manipulation a thorough filling of the smallest interstices of the object can be effected, and there need be no apprehension of shrinking or brittleness.

The author (who acknowledges the assistance of Dr. F. Blochmann) mentions some of the cases for which they have found the process very successful, viz. *Amphioxus, Cerianthus,* tape-worms, ambulacra of Echini, decalcified ambulacra of Holothurians, gelatinous parts of Ctenophora, Hydroid polyps, &c. Of large objects, such as cross-sections of *Amphioxus* and *Cerianthus,* sections can be made without difficulty of $\frac{1}{100}$ mm. in thickness. Of small objects, as the tentacles of *Cerianthus,* or entire Hydroid polypi, sections can be made of $\frac{1}{250}$ mm.; if Thoma's microtome is used, indeed under some circumstances even to $\frac{1}{500}$ mm. if the knife be placed rather obliquely to the object.

Perenyi's Hardening Fluid.[*]—Dr. J. Perenyi describes a new hardening fluid for embryological purposes which has given surprising

* Zool. Anzeig., v. (1882) pp. 459–60.

results. Its advantage consists in the fact that the ova do not become porous, and that the segmentation spheres, as well as the nuclei, remain fixed in their respective divisions. The ova may be cut like cartilage.

The composition of the fluid is :—

Nitric acid (10 per cent.)	4 parts.
Alcohol	3 ,,
Chromic acid (0·5 per cent.)	3 ,,

which after a short time forms a violet fluid.

In this the ova are placed for 4–5 hours, then for 24 hours in 70 per cent. alcohol, for a few days in strong alcohol, and for 4–5 days more in absolute alcohol.

For staining, either (1) the fluid itself, or (2) the oil of cloves, can be coloured.

The first method is more convenient because quicker, since the ova are hardened and coloured at the same time. The outer albuminous coat should, however, be removed, so that the staining fluid may penetrate better. Some colouring agents, such as eosin, purpurin, and aniline-violet, must be dissolved in three parts of alcohol before they are added to the hardening fluid, whilst others, such as fuchsin and aniline-red can be dissolved direct. Very beautiful preparations are made by colouring the fluid with picrocarmine or borax-carmine.

To get rid of the sediment produced by these agents the fluid must be filtered before the ova are laid in it. For washing, 5 per cent. alcohol is first used (5 hours), then ordinary alcohol (10 hours), and then absolute alcohol; for clearing, oil of cloves; and for mounting, Canada balsam.

By the second method the ova are hardened and cut, and the section placed on the slide wetted with one or two drops of coloured oil of cloves. In 5–10 minutes the latter is sucked away with filtering paper. The oil can be coloured with eosin dissolved in alcohol or with safranin.

If *entire ova* or embryos are freed from their outer albuminous coat and hardened, then taken out of the alcohol, left free until the alcohol is evaporated, and then wetted with a few drops of oil of cloves or turpentine, very excellent and *stable* preparations are obtained for the study of the outer segmentation.

Satterthwaite and Hunt's Freezing Section-cutter.*—Dr. T. E. Satterthwaite, in conjunction with Dr. J. H. Hunt, has devised a modification of the ordinary freezing microtome, shown in Fig. 134.

It consists of the brass cylinder S, made of rather large size and placed in the centre of a metallic box B. The length of the cylinder, with milled head D, is about 5 inches. The diameter of the well *a* is 1⅜ inch. Fitted round the cylinder is a plate glass for the knife to sweep over.

---

* Satterthwaite, T. E., 'A Manual of Histology.' 478 pp. and 198 figs., 8vo, London, 1881.

The knife A A is large, measuring 13 inches in length, including handle and $1\frac{3}{8}$ inches in breadth. It is slightly concave on both sides, and is fitted into a brass frame c, c, $7\frac{1}{4}$ inches by $3\frac{1}{8}$ inches. Two

Fig. 134.
strong brass springs and two sliding clamps hold it in place. The knife and frame are modifications of Dr. Curtis's plan.

The well is so large that it will hold an ordinary kidney after hardening, or, at least, so much of it that a section may be made of the whole organ at one sweep of the knife.

Each revolution of the milled head raises the preparation $\frac{1}{31}$ inch, and as it is divided into 30 divisions, each division represents $\frac{1}{930}$ inch. G is an indicator for marking the thickness of the sections, E E are tubes to fit in well, F F plugs, H H covers to the box, and K a binding screw to attach the latter to a table.

Windler's Microtome.[*] — This (Fig. 135) is a modification of Rivet's microtome, but retains little more than the principle of the original, i. e. the inclined ($c\ d$) and horizontal (b) slides attached to the vertical plate (a), these parts being all of metal. Instead of the ordinary clamp, which is very unsuitable for delicate objects, the inclined slide on the left supports a brass slide e, the under surface of which is lined with lead. Metal cases of different sizes l for the object to be cut, can be placed within it, and fixed by the screws n.

* Bericht wiss. Instrumente Berliner Gewerbeausstellung im Jahre 1879 (L. Loewenberg, 1880) pp. 309–12 (2 figs.).

The elevation of the slide as it is pushed forward can be read off on a scale on the vertical plate and a nonius.

The knife o is attached to a slide f (Fig. 136), which has an eccentric disk g on its upper surface. By turning this disk the knife,

FIG. 135.
which is fixed by the clamp-screw i, can be brought into any desired position.

There is one defect in all sliding microtomes, which consists in the tendency of the knife, when fastened only at the handle, to give

FIG. 136.
way at the free end of the blade on any resistance in the object. This defect is remedied by the metal bow k, the slit end of which passes through the axial screw h, while the front portion is attached to the knife by the screw p, by which means any displacement of the end of the blade is prevented.

Marsh's Section Knife.* — It is frequently suggested that the surface of the knife which has to glide along the cutting-plate of the

* 'Microscopical Section-cutting,' 2nd edition, 1882, pp. 32–3 (2 figs.).

microtome should be ground *flat*. This Dr. S. Marsh considers to be a most unsuitable arrangement, as a very little actual experience of section-cutting will speedily demonstrate. After many unsuccessful attempts to obtain a really good and reliable section-knife, he had one made, which has proved everything that could be desired.

Fig. 137.

The knife is shown in Figs. 137 and 138, the latter being a transverse section of the blade. It is furnished with a blade 4 inches long and $\frac{7}{8}$ inch broad, set in a square handle of boxwood, also 4 inches in length. The thickness of the blade at the back is not quite a $\frac{1}{4}$ inch, while *both* of the surfaces are ground slightly hollow. It is essentially necessary that the back and edge of the blade be strictly parallel to each other; that is to say, the edge must form a straight line, and both the edge and under side of the back must lie in the same plane, otherwise the knife, when in use, will have such a tendency to tilt over as to render its management extremely difficult. It is very easy to discover if this condition be fulfilled, for if, on carefully laying the flat of the blade upon a piece of level glass, every portion of both back and edge are found to be in close contact with it, the knife may in this respect be considered perfect.

Fig. 138.

Fig. 139.

Thanhoffer's Irrigation Knife.* — This (Fig. 139) devised by Professor L. v. Thanhoffer, and adapted either for free-hand cutting or with a hand microtome, consists of a blade (wedge-shaped in section) 11 cm. long and $2\frac{1}{2}$ cm. broad, a handle $12\frac{1}{2}$ cm. long and $1\frac{1}{2}$ cm. broad, and a tube (*a b*) for supplying water to the blade. This tube is attached to the back of the blade, and is there pierced with a row of fine holes; it also traverses the handle and terminates at its butt-end in a tap, to which an indiarubber tube may be attached. The fixed tube is supplied by the indiarubber feeding-tube with water from a vessel placed on a higher level or from a water-main. The water comes out of the small holes in drops
* Arch. Mikr. Anat., xix. (1881) pp. 315-7 (1 fig.).

and flowing together covers the blade with a layer of water along its whole length, even when it is lightly smeared with oil or has become greasy from the imbedding mass. It should, however, be kept in a horizontal position, or better somewhat inclined to ensure the water flowing over it. A vessel is placed under the hand to catch the water and also the sections which can be floated off by its aid, an important advantage of the instrument. If very large sections are required, the tube should not be directly attached to the blade, but a few millimetres above it. The section can then be floated off between the tube and the blade.

Differential Staining of Nucleated Blood-corpuscles.* — It has been urged against the differential staining of histological structures, that the process may induce an alteration which may be mistaken for the normal condition. That this is, in many cases, true, is beyond question, but Dr. A. Y. Moore considers that the exceptions are far too numerous to justify it as a rule. For some years past he has used a process for the double staining of nucleated blood-corpuscles, which causes no alteration, except of course in colour, and as the structure can be seen much better in a semi-transparent than in a more perfectly transparent body, the corpuscles thus stained offer advantages for study which are not found in those left unstained.

The fluids used for this purpose are two, viz.:—A. Eosin, 5 grains; distilled water, 4 drachms; alcohol, 4 drachms. Dissolve the eosin in the water and add the alcohol. B. Methyl-anilin green, 5 grains; distilled water, 1 ounce.

The blood should be spread upon the slide, by placing a drop upon one end and quickly drawing the smooth edge of another slide over it. This, if well done, will leave a single layer of corpuscles evenly spread over the central part of the slide. When the corpuscles on the slide are thoroughly dry, which will only require a few minutes, the slide should be "flooded" with stain A. This should be allowed to remain on for about three minutes, at the end of which time, it may be washed by gently waving back and forth in a glass of clean water. Before it is allowed to dry, the corpuscles should be again flooded, this time with stain B. After two minutes' exposure to this fluid, the slide should be washed, as before, and set away to dry. When dry, a drop of Canada balsam may be put upon the blood, a cover-glass applied and the whole gently warmed until the balsam spreads out properly. When hard it may be finished the same as is usual with balsam mounts.

If now examined with the Microscope, the corpuscles will be found to be well stained with red, while the nuclei and "leucocytes" will be a bluish-green. The granular appearance which is ordinarily seen in the nuclei, now shows with a vigour and sharpness which is difficult of description, while the whole corpuscle is as brilliant as a newly-cut ruby.

The Editors of 'The Microscope' (which since its commencement has contained much valuable matter), call special attention to the

* 'The Microscope,' ii. (1882) pp. 73–6 (1 col. pl.).

above method, working microscopists having long sought after a double-staining process for blood-corpuscles in which Dr. Moore is the first to succeed.

Flemming's Modified Method for Staining Nuclei.*—A method was published in 1875 by G. E. Hermann,† consisting essentially in overstaining with anilin or azotized staining matters, and subsequently extracting the colour, except from the nuclei, by means of absolute alcohol.

On this W. Flemming suggests some improvements. He finds the nitrogenized colouring-matters better than anilin colours for the purpose. Chromic acid is also preferable to alcohol for hardening, as it preserves the characters of the nuclei with more certainty. The preparations are fixed in chromic acid of ·1 to ·5 per cent. according to their nature. Only sections or thin, flat, and readily penetrable pieces should be used, and they must be thoroughly washed in distilled water. They are then placed for 12 to 24 hours in closed vessels in about 1 ccm. of a solution of safranin (or one of the other colouring matters mentioned below) absolute alcohol being used diluted by about the same amount of distilled water.‡ The object is now transferred to alcohol which frees it from part of the colour by shaking for a short time, and then into absolute alcohol and moved about for half a minute or more until no more colour is given off, and the object appears transparent and of the desired tint. If the object is to be permanently mounted it is placed in oil of cloves, but only so long as will admit of the tissue becoming penetrated, as it draws out the colour, and then mounted in cold dammar solution or balsam.

Out of a series of colours which were tested, *mauvein* and *fluorescent red*, while staining the nuclei well, are yet somewhat unequal in their action in that some nuclei will retain more colour than the rest. *Solid green* has the property of being very readily extracted from the intermediate substance of the nucleus, leaving the fibrillar network of the latter well stained. If this is decolorized, the nucleoli long retain the colour. *Fuchsin* gives excellent colours but somewhat paler than safranin, magdala, dahlia, and mauvein. *Bismarck brown* is unsuitable for the above process with chromic acid. *Safranin*, *magdala-red* (or naphthalin-rose), and *dahlia* (monophenylrosanilin) are the most constant and satisfactory in their action.

It must be noted, however, that practically the only application of the method is for nuclei-staining in chromic acid preparations. Where, however, it is desired to preserve and readily investigate the true natural structure in cell-nuclei and divisions of nuclei (which

* Arch. f. Mikr. Anat., xix. (1881) p. 317-30.
† Flemming subsequently stated (tom. cit., pp. 742-3) that the credit of priority so far as regards nuclei-staining with anilin colours, and decolorizing with alcohol, is due to Professor Böttcher, whose method is not, however, to be recommended for the same purposes as Hermann's, as he uses Müller's fluid and alcohol, stains the sections with a solution of rosanilin-nitrate in dilute glycerine, and after extracting the water with alcohol, clarifies with creosote.
‡ Dahlia is best used in aqueous or acetic acid solutions.

succeeds best with chromic acid), the above process is to be preferred to all others.   The only alternative method is hæmatoxylin, and that is much more uncertain in its action.

Iodine-green for Human and Animal Tissues.*—Dr. H. Griesbach recommends as the most useful of all anilin staining materials for this purpose, a new green material, tetramethylrosanilinmethyliodide, or "iodine green," or "Hofmann's green."   The composition of the solution for staining is preferably 0·1 gr. crystallized iodine green, and 35 gr. distilled water, though it may be varied according to the tint required.   The hardened tissue is placed for a few seconds in distilled water and then in the staining fluid, the action being almost momentary.   After washing in distilled water it is transferred to glycerine or absolute alcohol, cleared in oil of cloves or aniseed, and mounted in Canada balsam or dammar.

The objection to other anilin colours, that alcohol often draws the colour completely out in a few minutes, scarcely applies to iodine green, which is much more resistant.   Its chief advantages, however, are its rapid action, which adapts it excellently for demonstrations, and the fact that it also often gives different tints of the same colour to different parts of the tissues.   For instance in a section of the uterus of a deer, the epithelium is blue, the tubular glands dark green, the cylindrical ciliated cells of the single tubes show a splendid colouring of their nuclei, the longitudinal musculature is malachite green, and the connective tissue remains uncoloured. Hardened objects colour better than fresh.   Connective tissues and bones are not coloured at all or only very slightly.   Glandular organs, hardened in alcohol, are excellent objects.   The gland-cells are distinguished from the membrana propria by an intense and uniform colour.   Striated muscle (in alcohol preparations) is coloured a cantharides green, the sarcolemma remaining uncoloured.   Iodine green is also very useful for blood-corpuscles of vertebrates and invertebrates, for human white blood-corpuscles, and all kinds of isolated cells, spermatozoids, bacteria, &c.   Also for ganglion-cells and axis-cylinder.   In a section through human spinal cord in a chromic acid preparation (after a brief treatment with absolute alcohol and rinsing in distilled water) the horns of the grey substance were immediately coloured a uniform green, the *substantia gelatinosa* the same but brighter, the *substantia alba* being uncoloured.   This is an additional advantage of iodine green as it is well known with what difficulty chromic acid preparations take certain colours.

Professor Kollmann's statement of his satisfactory experiences with iodine green is added.

Teichmann's Injection-mass.†—The exact proportions of the materials used by L. Teichmann for his injection-mass ‡ are as follows :—

Red mass :—Prepared chalk 5 gr., vermilion 1 gr., linseed oil

* Zool. Anzeig., v. (1882) pp. 406–10.
† Abh. and SB. Naturw. Kl. Akad. Krakau, vii. (1880) pp. 108. Cf. Jahresber. Anat. u. Physiol., ix. (1881) pp. 11–12.
‡ Described generally in this Journal, *ante*, p. 125.

·9 to 1 cub. cm., carbon disulphide ·75 cub. cm.   For the injection of entire subjects by the aorta Teichmann uses first of all a thinner mass consisting of chalk, 500 gr., vermilion 100 gr., linseed oil 120 cub. cm., carbon disulphide 150 cub. cm.; he then employs a stiffer preparation of chalk 1000 gr., vermilion 200 gr., linseed oil 200 cub. cm., carbon disulphide 100 cub. cm. *White masses*, especially adapted for injection of lymphatics, have the following composition :—Zinc white 20 gr., linseed oil 3 cub. cm., ether 2 cub. cm.   By addition of colouring matters this mixture forms other combinations.   The following proportions are in general suitable for a *blue mass:* Zinc white 15 gr., ultramarine 1 gr., linseed oil 2 to $2\frac{1}{2}$ cub. cm., carbon disulphide 1 cub. cm.   The injection is made slowly by a syringe, the piston of which is provided with a screw-thread and is pushed gradually forwards by a twisting movement.   The linseed oil is first boiled for eight to ten hours, and no lead compounds are added to it.

Wywodzen's Injecting Material.*—D. Wywodzen has, he says, obtained admirable results by using thymol.   The proportions are :— thymol 5 parts, alcohol 45, glycerine 2160, and distilled water 1080.

Mounting in Pure Balsam.†—Dr. S. Marsh, although he cannot too strongly insist upon the use of benzol-balsam wherever practicable, yet points out that it sometimes happens in the mounting of substances of considerable thickness that, after all the benzol has evaporated, an insufficient amount of balsam is left behind to fill up the cavity between slide and cover.   In such cases, therefore, it is advisable to use pure balsam, which may be done in the following manner :—The object having been previously thoroughly dehydrated by immersion in absolute alcohol, it is to be thence transferred to a little *good* turpentine or benzol, where it should remain until perfectly transparent.   It is now to be placed in the centre of a slide which has been gently warmed, and a drop or two of fresh fluid balsam added, the greatest care being taken to prevent the formation of air-bubbles.   Should such arise they must be touched with the point of a heated needle, which will cause them to burst and disappear.   The chief difficulty of the process has yet to be encountered in the application of the cover, for it is during this procedure that the development of air-bubbles is most likely to take place.   This annoyance may, however, be entirely avoided by taking the simple precaution of dipping the cover into turpentine before it is applied, when it will be found that "you can't get air-bubbles even if you try."   The author adds that it is to the courtesy of Mr. J. A. Kay, late of Chatham, that he is able to give his readers the benefit of this practical "wrinkle."

Centering Objects on the Slide.‡—Dr. Marsh considers that the appearance of a slide is vastly improved if the preparation be placed

---

* St. Petersb. Med. Wochenschrift, No. 51.   Cf. Jahresber. Virchow and Hirsch for 1880, p. 2.
† 'Microscopical Section-cutting,' 2nd ed., 1882, p. 109.
‡ Ibid., p. 101.

exactly in its centre. This may readily be done in the following manner :—Take some very finely-powdered Prussian blue and rub it up in a mortar with a little weak mucilage, so as to form a thin blue pigment. A quantity of this should be made so as always to be at hand. A slide having been cleaned, the *best surface* is to be selected, and on the reverse side, by means of a self-centering turntable, a small circle is to be drawn with a camel's-hair pencil charged with the pigment. In the centre of this ring, but on the opposite side of the slide, the section is to be placed, when it, of course, will occupy a position exactly central. When the slide comes to be finished, the blue ring may easily be removed with a wet cloth.

Chalk Cells.*—For dry mounting of diatoms, and objects not much exceeding $\frac{1}{50}$ of an inch in thickness, Mr. F. Kitton has been using cells prepared in the following manner :—Wash some whitening in water to get rid of the coarser parts (foraminifera, sponge-spicules, &c.), or levigated chalk as sold by druggists can be used, and make a mixture about the consistency of cream with weak gum water; three or more applications will make cells of a sufficient depth. When dry go over them two or three times with a solution of Canada balsam dissolved in benzine. The cells should not be used until the balsam is quite hard; then place the cover (upon which the diatoms ought to be mounted) in position, and with a heated slide press it upon the cell; when properly attached the cement ring can be made in the usual manner.

Line and Pattern Mounting.†—Mr. H. Sharp gives the following directions for this kind of mounting, his slides thus prepared being said by Mr. W. H. Wooster to be " exquisite examples of manipulative skill."

" *Requisites* :—(1) One or two cat's or mouse's whiskers fastened on match-like sticks or fine rushes, with shellac rather than gum, with about $\frac{1}{4}$ inch free. I prefer to have one with the natural point, and another with the point cut back to where it is somewhat stiffer. (2) A good simple Microscope of some kind, either attached to a roomy stage-plate, with a mirror below and revolving plate above, or detached on some stand, but capable of being brought over a mounting table with mirror and rotating plate as above. My own is home-made, extremely simple, costing nothing but the trouble, and such as any one with a little ingenuity could make for himself. It consists of a piece of pine 9 inches long, 5 inches wide, and 1 inch thick, on three legs, with a hole in the centre, into which a wooden matchbox (with the bottom cut out) fits tightly, projecting a little above; over this fits a piece of slate just tight enough to rotate easily; beneath, a peg receives the mirror of the Microscope. This forms the detached mounting table. For the simple Microscope, I take the foot and tube pillar of the condenser, fit a piece of cane in this tube, drive a pickle-bottle cork stiffly on it, and fasten on this a horizontal wooden bar with a hole in the middle to fit on the cane, and another at each end

* Amer. Mon. Micr. Journ., iii. (1882) pp. 151–2.
† Journ. Micr. Soc. Victoria, i. (1882) pp. 94–6.

in which to fit the lenses, which are just the $1\frac{1}{2}$-inch and $\frac{1}{2}$-inch objectives, which give far better definition than common pocket lenses. (3) A steady hand. (4) Patience and perseverance.

Dry Mounts.—All diatoms and scales should be mounted on the cover, not the slide. Lay a clean cover on a slide and keep it in place by a drop of water between. As scales are larger than diatoms, it is well to begin with them. Put several on a slide in the ordinary way, pick out the ones wanted with a bristle under the simple Microscope, one at a time ; keep the cover flooded with moisture from the breath, and deposit the scales picked up wherever wanted in lines or patterns. They will readily leave the bristle for the wet glass, and can be pushed about quite easily. When the moisture dries off no stain is left, and the objects will adhere with sufficient firmness to resist anything short of a sharp jar. When the line or pattern is finished, mount in a shallow cement cell.

Balsam Mounts.—The cover must have a film of a gelatinous nature which is insoluble in balsam and its solvents. A thin aqueous solution of isinglass carefully filtered serves well. A single drop is placed on a clean cover, and spread out as thin as possible with a clean needle. It dries almost instantly in warm weather, and in a few seconds in winter. A diatom placed on this film and *gently breathed on* is securely sealed, and cannot be dislodged without moisture. Care must be taken to place the diatom in position while the film is quite dry ; then breathe on it ; allow the film to dry again ; then place another diatom, and so on till the line or pattern is finished. If any of the diatoms are thick or likely to be crushed, stick three bits of cover-glass under the edge of the cover with gum, and place a dot of gum on each before placing the cover in position on the slide. This, when dry, will keep the cover in its place while introducing the balsam, before doing which allow a little benzine to run under by capillary attraction, which soon displaces the air from the diatoms. Then apply a little balsam to the edge of the cover and a bit of blotting-paper to the opposite edge. This draws away the benzine, and the balsam follows and takes its place. Another plan is to gum a piece of good cream-laid paper on the slide, centre on the turn-table, and make two cuts through the paper, removing the middle and outer portions and leaving a ring of paper to form a cell as large as the cover ; then cut two small openings in opposite sides of the ring, gum the top of the cell and insert the prepared cover on the gummed surface. When dry apply benzine to one of the small ' sluice gates,' and then balsam as before. Put the slide in a warm place for several days, and finish off with white, black, or coloured varnish to fancy. Winter is the best time for dry mounts, as the breath dries off too soon in hot weather ; and summer is the best time for the balsam mounts, as it is difficult in the winter to keep the breath from moistening the isinglass at the wrong time. The cement cells should be quite dry and hard before mounting, or a dewiness will appear and ruin the object. Soften the cement over the lamp, press the cover down till it sticks all round, let stand a day or two, and finish off. No doubt the diatoms would be more secure if burnt

3 c 2

on the cover in the dry mounts, and possibly that process would be sufficient for the balsam mounts without the film of isinglass, as stated on p. 68 of Davies' ' Manual of Mounting.' "

Mr. Sharp has tried several kinds of mechanical finger, but declares he " can do the work quite as well and in less than half the time " by the method described above.

Mr. W. M. Bale also discusses * the subject of mounting diatoms in symmetrical groups in continuation of a previous paper † in which he described the process for valves which are very small and flat, and are to be mounted dry. Large or uneven diatoms are, however, liable to leave the slide at the least jar, and must therefore be attached with some cement; while *any* diatoms which are to be mounted in balsam must be fixed to the slide or cover with a cement not soluble in the turpentine contained therein. In these cases, a minute drop of clear gum may be deposited near the centre of a clean slide, and thinned with a drop or two of water, the whole being spread backwards and forwards over the slide with the blade of a knife till none appears to be left in the centre where the objects are to be placed. The diatoms are then arranged on the slide in the usual manner after breathing on it, and when dry they will adhere to its surface, after which they may be covered in the ordinary way. With dry mounts especial care must be taken that the merest invisible film of gum remains on the slide, the appearance of the diatoms being spoiled if they are saturated with gum or any similar material.

For transferring valves from one slide to another mounted bristles are best, one rather stout for large diatoms, and another not thicker than a human hair, and somewhat curved for lifting small valves and remaining particles of dust. Bristles are, however, too elastic for moving the diatoms into the exact position, for which a fine needle is almost indispensable.

When the objects are to be mounted in balsam, the slide should be allowed to dry, and a small drop of carbolic acid placed on the diatoms, which are then to be examined with the Microscope, as it frequently happens that the gum, if not thin enough, seals up the minute cells in the valve, or even the whole cavity beneath it, preventing the entrance of the acid. In this case a drop of spirits of wine placed on the diatoms will usually find speedy entrance and dispel all bubbles, and while the diatoms are still wet with the spirit the carbolic acid may be placed upon them. Gentle warmth will then evaporate the spirit, leaving the acid, and it only remains to apply a small drop of balsam and a cover, taking care, if any of the valves are very convex, to provide rests to prevent the cover from crushing them. It is better to let the balsam fall on the diatoms than to apply the cover first, and let it run in, as it very often carries in with it particles of dust, cotton fibres, &c., which may be on the slide or the edge of the cover, and which are apt to come in contact with the diatoms and remain there. The running-in process is only necessary when the valves are not cemented to the slide, and when,

* Journ. Micr. Soc. Victoria, i. (1882) pp. 97–9.
† Ibid., i. (1881).

consequently, balsam let fall on them would be almost certain to disperse them.

In most cases it is advantageous to mount the diatoms on the cover, which is easily done by first fastening it to a slide with a drop of glycerine, which will not evaporate during the process of mounting, and is easily removed afterwards. Large diatoms, such as *Arachnoidiscus*, when mounted on the slide and examined by reflected light, are apt to show a slight haze surrounding the group, instead of the intense black ground which should be presented when all light is shut off from below the stage. This is caused by reflection from the under surface of the slide, and can be avoided by mounting on the cover and placing some dead-black material at the bottom of the cell.

If Polycistina or Foraminifera are to be mounted, a thicker layer of gum should be placed on the slide than for diatoms, as these objects, from their peculiar forms, have usually a very small part of their surface in contact with the slide.

The author considers "this branch of microscopic art as quite legitimate" where selected species have to be mounted and provided scientific value is not sacrificed to mere prettiness. He also says that he has recently used the gum process with all balsam-mounted diatoms even when they are not arranged symmetrically for the sake of the security it affords against the valves being displaced by slight pressure on the cover-glass, or by the slide being kept in other than a horizontal position, also for the advantage of being able to mount the valves in different positions so often necessary in order to get an exact idea of their true form.

Kain's and Sidle's Mechanical Fingers.[*]—Mr. C. H. Kain describes a simple mechanical finger for use with any Microscope that has the fine adjustment on the nose-piece. It is designed to obviate the inconvenience of the one described by Professor H. L. Smith,[†] which requires the loosening and tightening of the objective for the purpose of focussing.

It consists essentially of a slotted bar (Fig. 140), which may be firmly clamped to the upper (immovable) bar of the fine adjustment by means of a milled-headed screw. Through the end of this is fastened a round rod, at such a distance from the objective that, when lowered, the end will not strike the stage. Over this rod slips a split tube, to which is soldered, at an angle, a smaller tube. Through the small tube passes a rod carrying a glass thread at its extremity. This rod is easily rotated by means of a milled head. The capillary glass thread is attached to the extremity by means of beeswax. There is no revolving collar, as it is quite unnecessary, especially when the Microscope is provided with a revolving stage. By dispensing with the revolving collar and making all movements depend entirely upon the adjustments of the Microscope, greater stability and accuracy in working are secured.

---

[*] Amer. Journ. Micr., vi. (1881) pp. 149–51 (1 fig.).
[†] See this Journal, ii. (1879) p. 952.

The author says:—

"To use the finger, the point of the glass thread is first brought into the focus of the objective, or nearly so, by sliding the tube on the vertical rod, and pushing or pulling the rod carrying the thread until the desired position is attained.   It is not difficult to do this,

Fig. 140.
and having once been done by hand, it does not have to be repeated, as all further movements are made by the adjustments of the Microscope.   Supposing now the point of the glass thread to be in focus; by means of the fine adjustment throw the focus *ahead* of the point, then, by means of the coarse adjustment, rack down and search for the object you wish to pick up. Having found the object desired, again bring the point of the thread into focus by means of the fine adjustment; then rack down with the coarse adjustment and pick it up. Now rack back with the coarse adjustment, remove the slip on which the material is spread, and place your prepared slip or cover upon the stage.   Again, by means of the fine adjustment, throw the focus ahead of the object, rack down with the coarse adjustment, and search for the spot where you wish to deposit the object, and having found it, again focus the object, then rack down with the coarse adjustment, and when the object touches the slide and has been placed in proper position, fix it by means of a very gentle breath.   I prefer this mode of fixing instead of the arrangement of tubes proposed by Professor Smith.

I coat the surface of the cover or slide upon which the diatoms are to be fixed with an exceedingly thin film of gelatine, prepared thus:—Dissolve 2 drachms of Cox's gelatine in 10 drachms of acetic acid by the aid of a gentle heat.   When the gelatine is thoroughly dissolved, add 1 drachm of alcohol and 1 oz. of distilled water; stir well until thoroughly mixed, let stand some hours, and filter through the finest filtering paper.   Keep in a glass-stoppered bottle.   To coat

the cover or slip I dip a small needle in the solution and wipe it once flatwise across the glass.

There are many little wrinkles which the worker will acquire from time to time. One of the most important of these is the art of using the finger as a lever for moving diatoms or other objects into position when very slight movements are necessary. To do this, move the slide by hand until the point of the finger is just behind the object to be moved; then, by racking down with the coarse adjustment, the glass point pushes the object ahead of it. By a succession of pushes the object may be moved into any desired position. The coarse adjustment may be used in a similar manner for turning diatoms on edge or upside down, by pushing them against some fixed object and forcing the glass point under them. By using a point rather firmer than usual, the valves of a diatom may be separated. To do this I usually fasten the diatom on a slide which has been coated with gelatine, and when it is firmly fixed, the upper valve may be punched off without much difficulty.

Another wrinkle, and quite a valuable one too, is what might be called a scientific use of the imagination. Many cannot work a mechanical finger well without an erecting eye-piece, on account of all movements appearing to be reversed. This difficulty will disappear if the worker will just imagine, as he holds the stage and moves it, that he is holding the finger and moving it; all motions will then appear to be perfectly natural. I might state here that a mechanical stage is not the best for this kind of work.

There is a popular misconception in regard to the mechanical finger which it may not be amiss to mention. Many regard it as a kind of scientific plaything—an instrument used merely for arranging diatoms so as to form pretty slides. I have no doubt but that it will come eventually to be regarded as one of the microscopist's most valuable accessories, and one which every worker will require. It may be used not only in handling and studying diatoms, but also other objects which are too small to be handled in the ordinary way. In studying the Infusoria, for instance, a drop of water containing them may be placed in a concave slide, then, when the water has been almost evaporated, or has been removed by means of bibulous paper, the Infusoria may be picked out with the mechanical finger and studied, or deposited on a slip for mounting. A firm thread of dark-coloured glass is best for this.

In studying diatoms, a mechanical finger is almost indispensable, for it may safely be said that one is not thoroughly acquainted with a diatom until he has turned it over and viewed it in all its aspects. In mounting diatoms for study it is well to mount a number of the same kind in various positions, so as to display the various spines, undulations, or other peculiarities. How often it happens, too, that in a mixed gathering of diatoms—and it is not easy to obtain pure gatherings—we find a rare frustule which we should like to preserve. By means of a mechanical finger the frustule may at once be selected and mounted.

When one wishes to arrange diatoms so as to form symmetrical

figures, an eye-piece micrometer will be found very useful, not only in selecting diatoms of uniform size, but also in determining their position. A circle ruled in squares and used in the same way as the eye-piece micrometer will be found still more desirable. It is a good idea to keep a number of glass points, of different degrees of fineness, ready prepared; that is, attached to little rolls of beeswax, so that if a point is unsuited for a particular work another can be substituted in a moment."

Messrs. Sidle have also modified the mechanical finger described *ante*, Vol. II. (1879) p. 952, by adding a micrometer-screw with a milled-head nut for moving the point of the glass thread in and out of focus, thus avoiding unscrewing the front of the objective. The sliding rod has been retained for getting it approximately into position. By a later improvement the glass "hair" or bristle is carried on a second rod through a sleeve attached to the first or vertical one, nearly at right angles. Thus, by the rotation of the second rod, and of the entire apparatus around the axis of the Microscope, the diatom may be brought into any desired position.

Venice Turpentine as a Cement.[*]—Professor C. B. Parker says that his attention was called to a substance known in the Pathological Laboratory, at Vienna, as *Venedischer Damarlack* (Venetian dammar varnish), which was exclusively used for sealing and finishing glycerine mounts. No such substance is known to the American trade, but he found after experimenting that Venice turpentine, prepared as presently to be described, if not identical, at least answers every purpose equally as well. The following are the directions for preparing the turpentine. Dissolve true Venice turpentine in enough alcohol, so that after solution it will pass readily through a filter, and, after filtering, place in an evaporating dish, and by means of a sand bath evaporate down to about three-quarters of the quantity originally used. The best way to tell when the evaporation has gone far enough, is to drop some of the melted turpentine, after it is evaporated down to about three-quarters its original volume, into cold water, and on being taken out of the water if it is hard, and breaks with a vitreous fracture on being struck with the point of a knife, cease evaporation and allow to cool.

Square covers should be used, and the cover-glass being adjusted with the usual precautions observed in glycerine mounting, the surplus glycerine, if any, should be wiped away, and the slide so placed that the edges of the cover-glass are plainly seen. A piece of wire, No. 10–12 (copper is the best, as it gives to the turpentine a greenish tinge), is bent at right angles, the short arm being just the length of the cover-glass. The wire is heated in the flame of an alcohol lamp, and plunged into the prepared turpentine, some of which adheres to it. The wire is then brought down flat upon the slide at the margin of the cover, and the turpentine will distribute itself evenly along the entire side of the cover. The same process is to be carried out on each of the other three sides. Any little unevenness may be removed by passing the heated wire over it.

* Amer. Mon. Micr. Journ., ii. (1881) pp. 229–30.

The advantages claimed for this substance, over all others used for a similar purpose, are that it is secure. Such thick objects as the female organs of *Vermicularis* and *Tricocephalus dispar* in glycerine, are now as tight and firm as when first mounted in 1878. It hardens immediately. The moment the heated wire is removed, the specimen may be cleaned and handled without fear, a great advantage over such slow-drying fluids as dammar and balsam. It never runs in, as white zinc and other cements are apt to do.

Metal Caps for Glycerine Mounts.* — Mr. F. Enock protects objects mounted in fluid from damage by external pressure by a small metallic ring of angular section fitting closely round the outside of the cell and at the same time slightly overlapping the cover-glass, entirely closing in the rim. He writes: — "I have had much bitter experience with preparations mounted in glycerine, which suffer injury from clumsiness in handling, more than the fault of expansion; for after a preparation has been mounted two or three years, the cement becomes very hard, and if injured by a fall, or knock against the Microscope, starts a leak. The number of preparations ruined by my customers in this and other ways, prompted me to find a remedy, or to lessen the chance of injury. I have now devised the metal caps, which so far have stood the heavy thumps of the Post-office men, and all the clumsy treatment which many give them. The caps are made to fit Pumphrey's vulcanite cells, as they are the only cell to be depended upon for size and shape. I never use any other. My plan of using these caps is as follows:—After having fixed the cover properly and without leakage, I wash the preparation under the tap until all traces of glycerine are removed, then run a good thick ring of any kind of cement round the edge of the cover and cell, finally dropping on the cap, when the mount should be placed aside for a week, so that the cement or varnish may properly set. I use these caps for all deep cells, as they prevent the cover from being pushed off, and am having some made half the depth of those sent, for shallow cells."

FIG. 141.
Nassau Adjustable Spiral Spring Clip.—This clip, the construction of which is sufficiently explained by Fig. 141, can be instantly adjusted by a screw movement to any degree of pressure required upon the cover-glass in mounting.

Green Light for Microscopical Observations.—We briefly alluded to this subject in the previous volume,† but it may be well to record somewhat more specifically that Professor T. W. Engelmann strongly recommends the use of green light for delicate observations; it not only spares the eyes, but also gives images which are markedly sharper than

---

* North. Microscopist, i. (1881) pp. 297–8. Journ. Quek. Micr. Club, i. (1882) p. 40.
† This Journal, i. (1881) p. 224.

those given by white light. Blue light is less to be recommended, and red is altogether to be rejected.

M. Flesch* points out the disadvantage of green glass for light modifiers, as it absorbs the red rays almost completely, so that the colouring in carmine preparations is not visible, and that of other parts of the objects becomes indistinct.

Photo-Micrography.†—Professor C. H. Kain doubts "whether microscopists in general are fully aware of the extent to which late improvements in dry-plate photography have simplified the work. To the investigating microscopist it is almost absolutely essential to be able to permanently preserve the results of his observations. This is usually done by the aid of the camera lucida, and the zealous worker will often sit for hours with his eye fixed at the instrument laboriously striving to represent an object, and if he is not well skilled in the use of the pencil his labour is frequently almost useless, so inaccurate is the result. By far the greater part of this labour may be saved, at an expense so trifling, and with results so satisfactory, that he thinks the time is at hand when every working microscopist will regard a dry-plate photographic outfit as a necessary part of his equipment.

"The wet-plate process is cumbersome, and not well adapted to the wants of the microscopist, but the dry plates now in the market are admirable, not only for their great sensitiveness and beautiful results, but also for the ease with which they can be manipulated. They can be purchased so cheaply, that it can scarcely pay the microscopist to prepare them himself. Some of the great advantages which they possess are the following :—

"1. They can be kept for any length of time and used as occasion requires.

"2. If not convenient to develope the plate at the time the exposure is made, it can be put away and developed at leisure even after an interval of weeks.

"3. No dangerously poisonous chemicals are necessary in the developing process.

"4. They are so sensitive that the light of an ordinary kerosene lamp (preferably a student lamp) is amply sufficient to photograph objects with all powers not higher than $\frac{1}{2}$-inch objectives." Probably a $\frac{1}{4}$-inch objective could be used by properly arranging a system of condensers.

The author adds : "As some who desire to experiment in this line may require a starting-point as regards the matter of exposure, I would say that with the light of a student lamp, and using a single condenser, I have found that from $1\frac{1}{2}$ to $2\frac{1}{2}$ minutes with a 2-inch, $2\frac{1}{2}$ to 5 with a 1-inch, and 4 to 7 minutes with a $\frac{1}{2}$-inch objective are about the proper times when the A eye-piece is in and using what are known as Carbutt's rapid (B) plates, No. 468. When the eye-

* SB. Phys.-Med. Gesell. Würzburg, 1882 (sep. repr.).
† Amer. Mon. Micr. Journ., iii. (1882) pp. 71-2.

piece is not used about one-half of that time is required. Of course the time of exposure will vary somewhat according to the density or transparency of the object, and if stained, according to the character of the colouring matter."

At a meeting of the Camden (U.S.A.) Microscopical Society,[*] Mr. J. Carbutt took a negative from a spider's foot with a 2-inch objective and an exposure of 2 minutes, and from a sheep's tick with an exposure of $1\frac{1}{4}$ minute, the shorter exposure being due to the object being much less dense and yellow. " B " dry plates were used in both cases.

Woodward's Photographs of Amphipleura and Pleurosigma.— It will be remembered that Dr. J. J. Woodward forwarded to the Society, in illustration of papers by him,[†] fourteen photographs of *Amphipleura pellucida*, and three of *Pleurosigma angulatum*.

As these photographs are not generally accessible, it may be useful to note that they were reproduced by a heliographic process (on a scale of $\frac{1}{3}$) in the ' Arch. f. Mikr. Anat.'[‡] which is to be found in many libraries in this country. The plates are accompanied by an abstract of Dr. Woodward's papers by C. Janisch.

Microscopical Examination of Handwriting.—Dr. J. H. Wythe, of San Francisco, maintains, as we have already recorded,[§] that every man's handwriting is infallibly distinguished by three characteristics, that may be detected by the Microscope while they escape the eye, viz. :—rhythm of *form*, dependent on habit or organization ; rhythm of *progress*, or the involuntary rhythm, seen as a wavy line or irregular margin of the letters ; and rhythm of *pressure*, or alternation of light and dark strokes. The proper microscopical examination of these three rhythms, under a sufficient illumination of the letters, cannot fail, he believes, to demonstrate the difference between a genuine and an imitated signature.

Professor D. T. Ames,[||] while believing Dr. Wythe's views to be sound, " prefers to more simply define the three characteristics as *habit of form, movement, and shade ;* these, in connection with other attendant peculiarities of handwriting, furnish a basis sufficient to enable a skilful examiner of writing to demonstrate the identity of any handwriting with a great degree of certainty.

" In extreme cases, and especially skilfully forged signatures, the aid of the Microscope will be necessary for a proper examination, but for the greater proportion of cases of questioned handwriting a common glass, magnifying from ten to twenty diameters, will serve much the better purpose, as it is amply sufficient to reveal the characteristics of the writing, while its greater convenience of use and broader field of view are greatly in its favour.

" In the writing of every adult are habits of form, movement, and

shade, so multitudinous as in the main to be unnoted by the writer, and impossible of perception by any imitator.   Hence, in cases of forged or imitated writing, the forger labours under two insuperable difficulties, viz. the incorporation of all the habitual characteristics of the writing he would simulate, and the avoidance of all his own unconscious writing habit, to do which in any extended writing we believe to be utterly impossible.

"How far this inevitable failure may be discovered and demonstrated depends upon the skill of the forger, and the acuteness of the expert."

Examination of Sputa.*—In suspected cases of phthisis where it is very desirable to know the progress made by the disease, great aid may be procured by an examination of the sputa of the patient.   It is now a recognized fact that phthisis has been diagnosed, and is diagnosed in this way, weeks and months before other signs are manifested.

As expectorated ingredients in the sputa, one finds remains of food, starch-granules, epithelium, air-bubbles, mucus-cells, pus-cells, blood-corpuscles, large granular cells, and, perhaps, pigment-cells.   If now besides these are found fragments of lung tissue, as yellow elastic fibres, it shows that there must be a disintegration of the pulmonary tissue, a condition which must denote serious trouble.   If these fibres are not found it does not by any means prove that serious trouble may not exist, but their presence is very significant.

If the patient is in the habit of using tobacco, it should be denied during the collection of the sputa, as the fibres of the leaf might mislead and cause a wrong diagnosis.   If the amount of sputa is small, then all raised during the twenty-four hours should be saved. If large, that first raised in the morning should be preferred.   Any little greyish masses should be chosen and placed at once under the Microscope.   Acetic acid will clear up the mucus, &c., and render more distinct the yellow fibres if they are present.   If this examination reveals nothing, the following method should be adopted :

Make a solution of sodic hydrate, 20 grains to the ounce of water. Mix the sputa with an equal bulk of this solution and boil.   Then add to this mixture four or five times its bulk of cold water.   If possible, pour into a conical-shaped glass and set aside.   Soon the yellow fibres, if present, will fall to the bottom ; from where they can be drawn up with a pipette and examined.   Several slides should be examined at a single sitting, and the examination should be repeated every few days until the presence or absence of these fibres is satisfactorily demonstrated.

Trichina-Examinations.—The microscopical examination of pork for *Trichinæ* is, as is well known, obligatory in many parts of the Continent.   In Germany in particular such an inspection is encouraged pecuniarily and punishment awarded in case of negligence.

* Cincinnati Med. News, x. (1881) pp. 550-1.

An inspector was, in 1874, sentenced to six weeks' imprisonment for having overlooked the presence of *Trichinæ* in an animal which he had inspected. In Italy also pork is similarly examined.

We subjoin a copy of an official notice on the subject of such examinations.*

OFFICIAL NOTICE.—*Directions for the Microscopist in the Examination of the Flesh of Pigs for Trichinæ.*—1. Approved physicians, veterinary surgeons, and apothecaries are without examination officially admitted as microscopists on application to the city magistrate according to the demand for their services, such appointment being revocable; other persons are only admitted after undergoing an examination as to their fitness before the royal district physician.

2. Every microscopist must have a Microscope, the efficiency of which has been examined by the royal district physician, and its lowest power must not be under 40 nor over 60 diameters. A Microscope which has not been examined or which has been found unserviceable may not be used for Trichinæ examinations.

3. The microscopists are appointed to certain districts, and are bound to undertake in their districts, or in those for which they are temporarily appointed as auxiliaries, examinations when required and without any delay, between the hours of 6 in the morning and 8 in the evening, from the 21st March to the 21st September, and between 8 in the morning and 8 in the evening from the 21st September to the 21st March.

4. The samples of flesh to be used for examination are to be taken from six places in the case of whole pigs, viz.:—

    (1) From both sides.
        (*a*) From the eyes, or the masticatory muscles.
        (*b*) From the diaphragm.
    (2) From one side.
        (*a*) From the muscles of the larynx or the loins and stomach.
        (*b*) From the intercostal muscles, in single portions of flesh and hams, to be taken from at least two places by the microscopist himself.

From each sample of flesh at least five preparations which can be put under a covering glass are to be prepared.

5. The result of the examination is to be entered by the microscopist, with his name and the date added, under the proper heading in the flesh-book, which the butcher has to keep. To private persons he has to give the certificate prescribed by § 4 of the Trichinæ examination regulations.

6. If a pig or a portion of one is found to be trichinous, the same must be guarded from being changed by a plain mark set upon it. Notice must be given immediately to the royal district physician, and the preparation in question produced to him for subsequent revision; immediate notice is also to be given to the police authorities.

* Zeitschr. f. mikr. Fleischschau, i. (1880) pp. 124–5.

7. The microscopist must keep a book in which he shall enter the examinations made by him in the following form :

1	2	3	4	5	6	7
Consecutive No.	Date when slaugh-tered.	Description of the pig ex-amined, as to sex and age, or specifica-tion of the part of flesh examined.	Name and residence of the party who brought the animal to be slaugh-tered, or who gave the order.	Day and hour of the micro-scopical ex-amination.	Attestation of the microsco-pist as to the result of the microscopical examination with respect to Trichinæ and flukes.	Remarks.

If flukes or anything else prejudicial to the use of the flesh for food is found to exist, immediate notice thereof is to be given to the police authorities, and a report made in the form of columns 6 and 7.

8. Hams or pieces of pork examined must always be marked with a brand. Whole animals are to be branded in different parts of the skin when it is required by the owner.

9. A microscopist may not undertake in one day more than twenty examinations of whole pigs. The examination of three hams and three pieces of pork are reckoned, for the purpose of examination, as equivalent to one whole pig.

10. If any case of evasion of microscopical examination becomes known to the microscopist, he must give notice to the police authorities.

Fees payable for examining pigs for Trichinæ.—By virtue of § 8 of the local police regulations for the microscopical examination of pigs' flesh for Trichinæ, the fees payable to the microscopist are hereby fixed until further notice, and shall be as follows :—

1. For examining a pig . . . . 1 mark (= 1s.)
2. When several pigs are examined at the same time in one and the same place, for the first animal . . . . . 1 mark.
   For every subsequent ditto . . . 70 pf.
3. For a piece of pork or a ham . . . 30 pf.
   For examining at the same time several pieces of pork or hams in the same place:
   For the first piece . . . . . 30 pf.
   For every additional piece . . . 20 pf.
   The minimum charge, however, for the ex-amination of only one or two pieces of flesh or hams when not taken to the dwell-ing of the microscopist shall be . . 70 pf.

Some of the regulations are more elaborate than the preceding, those for Silesia, for instance, occupying twelve pages,* and including regulations for the examination of candidates, and instructions as to making and examining the preparation, and using the Microscope. The latter are as follows :—

* See Wolff, E., ' Die Untersuchung des Fleisches auf Trichinen,' pp. 14–15. 74 pp., 1 pl. and 2 figs., 6th ed., 8vo, Breslau, 1880.

" The tube of the Microscope must be tested each time before it is used to see whether any foreign body is enclosed in it, or one of the diaphragm stops has got on edge.   The draw-tube must be pulled out before use.   The glasses of the lens-systems of the instrument, and also the illuminating mirror, are to be carefully cleaned with a dry hair-pencil, or with very soft wash-leather.

With illumination by light from below, care must always be taken that it falls as horizontally as possible on the mirror. The Microscope should therefore not be brought nearer to the window than is absolutely necessary.   Dazzling sunlight is a disadvantage.   Double windows are an impediment to the examination.

Only in exceptional cases are examinations to be made by lamplight, and on such occasions a low petroleum lamp is to be used, with a glass shade, the lower part of which is closed either by porcelain-glass or ground white glass.

Those who desire to examine with low powers and light from above must bring the Microscope near the window in order to obtain as much incident light as possible.

The hours of bright daylight are to be chosen for the examination, and the work should be done, if practicable, at an open window.

The greatest care must be used in attaching to the tube the systems selected, and the operator must make sure that the tube is exactly centered.   Particular attention must be given to the estimation of the focal distance.   With low powers the focal distances are much greater than with high-power objectives, and the tube will therefore require a greater distance between it and the preparation, in proportion as the powers used are low.

The preparation to be examined is now placed, with the cover-glass on, in such a position on the stage that it lies as nearly as possible over the centre of the opening of the stage.   The largest diaphragm aperture is then to be brought underneath, and full direct light reflected by the mirror up the tube.   Whilst the eye, kept as near as possible to the eye-piece, is directed towards the object, the tube is cautiously moved up and down till the image appears clearly."

The Prefect of the Seine has also recently established a course of six lectures for the teaching of micrography, and an examination has been instituted for inspectors for detecting Trichinæ in the substance of pork and ham of American or German origin imported into France.

Continuous Observations of Minute Animalcula.[*]—E. Holmes having found some difficulty in keeping minute living objects under observation on account of the water evaporating, and also that any attempt at a supply produced currents which washed away all very small organisms, was led to put upon a slide a small quantity of water, and a very minute portion of plant, not using enough water to occupy all the space under the cover-glass, but leaving part of it occupied by air.   A ring of paraffin wax was put round the cover, thus sealing up the contents, embracing rotifers and diatoms, several hundred species in all.   At the expiration of a week they were still

* Sci.-Gossip, 1882, p. 138.

alive. The same process tried on *Cyclops quadricornis* (only with a shallow cell to contain a depth of water just enough not to squeeze the creature betwixt slip and cover) allowed young *Cyclops* to hatch out of the eggs in each instance some dozens in number, and very active, the old and young doing well at the end of forty-eight hours. The author adds:—" Obviously if one finds a rare minute creature, and wishes to send it to a friend for inspection, one may seal it up in this way without the risk, or it may be, certainty of losing it involved in placing it in a tube. It will live comfortably enough during transmission by post, or during the few hours required to carry it to the meeting of a society, or a friend's house. It is even safer in transmission, because the quantity of water used is not enough to shake about as it will in tubes or small bottles, and half a day's fishing to find it again is dispensed with, as it is sure to be on the slide."

Microscopical Examination of Textile Fabrics.*—Prof. C. Cramer has paid special attention to the detection of adulterations of the three following kinds in textile fibres.

1. Detection of Chinese grass (*Boehmeria nivea*) in silk. In floss-silk containing adulteration to the extent of from 50 to 75 per cent., ordinary chemical tests are unable to detect the nature of the admixture. Microscopical and microchemical examination prove the presence in the silk of bundles of bast-fibres of *Boehmeria nivea*, which are snow-white, shining and rigid, in contrast to the yellow and more flexible threads of silk. They are at most 18 cm. in length, while the silk threads are much longer; the diameter of the latter varying between $0 \cdot 0076$ and $0 \cdot 0214$ mm., that of the former between $0 \cdot 0061$ and $0 \cdot 00643$ mm. The natural ends of the bast-fibres are finely pointed, of the silk threads abruptly broken. The bast-fibres have a cavity, sometimes too small to be measured, but varying to a width of $0 \cdot 055$ mm.; silk is solid and homogeneous. The walls of the former are swollen and knotted in places, exhibiting in sulphuric acid clear longitudinal striæ; silk has nothing of the kind. In polarized light the bast-fibres show bright colours in the middle and at the margin; the polarization colours of silk are dull and not visible in the middle. In addition, the bast-fibres readily take fire; are not coloured yellow by nitric acid, while silk is; remain white when warmed with Millon's reagent, silk becoming red; with iodine and sulphuric acid they turn a copper-red, violet, or indigo-blue colour, accompanied by swelling, while silk becomes golden-yellow or brown; and boiling with concentrated soda-ley does not attack the bast-fibres; this last test being used to determine the extent of the adulteration.

2. Detection of shoddy in woollen fabrics. In a specimen of blue cloth, the wool having been removed by potash-ley, were found vegetable adulterations, consisting of unconnected bast-fibres, and thickish branched and anastomosing bundles of bast-cells $0 \cdot 006$ to $0 \cdot 015$ mm. in thickness, and not more than $0 \cdot 2$ to $0 \cdot 65$ mm. in length. These

* Cramer, C., 'Drei gerichtliche mikroskopische Expertisen betreffend Textile-Fasern.' 29 pp., Zürich, 1881.

last are derived from the fruits of various species of *Medicago*, especially *M. apiculata*, *denticulata*, and *Tenoriana*. The unconnected bast-fibres are probably from the leaves and epidermis of the stem of *Gynerium argenteum*, the most abundant grass in the pastures of Uruguay, Buenos Ayres, Paraguay, and Entre Rios, from which the wool may have come. The animal fibres were entirely wool.

3. Distinction between fibres of hemp and flax. The bast-cells of hemp and flax present no character by which they can be distinguished with certainty under the Microscope, even with the assistance of reagents. The bast-cells of flax are slightly more slender, but this cannot be relied on. A transverse section of both is usually circular, but occasionally polyhedral or flattened, and the size of the cavity affords no certain criterion. The formation of layers is slightly more obvious in hemp; but the difference is too small for practical use. The pores described by Schacht and Wiesner are believed by Cramer to be transverse folds of peripheral layers of cell-wall. Both fibres are coloured blue by iodine and sulphuric acid; ammonio-oxide of copper causes appearances of swelling in both. Hemp-fibres are not always coloured yellow by sulphate of anilin. The best distinctive character of the two fibres is the substances which accidentally accompany them. The parenchyma which surrounds hemp-bast contains numerous crescent-shaped clusters of crystals of calcium oxalate, which the bast-parenchyma of flax does not. Among the bast-cells of hemp are also elongated cells widened tangentially, filled with an intensely red-brown endochrome, sometimes composed of connected ribbon-shaped masses, sometimes broken up into quadrangular pieces, insoluble in boiling potash, cold alcohol, ether, turpentine-oil, and benzin, offering long-continued resistance to concentrated sulphuric and hydrochloric acids, and rendered colourless by Schulz's solution. The epidermis of the two plants also presents differences. That of flax has numerous stomata and no hairs; that of hemp few stomata and unicellular hairs thickened in a warty manner. These characters are always easy of detection.

The Microscope in Engineering Work.[*]—The following is a paper by R. Grimshaw, read at a meeting of the Franklin Institute.

"The specimens shown are intended to outline a method of using the Microscope as an aid to the testing machine in estimating the value of structural materials. While it is not intended to suggest that the Microscope will determine definitely the elastic limit, nor even the breaking strain of structural materials, it is designed to convey very distinctly the idea that the Microscope may be used for preliminary investigations which will determine whether or not the material is good enough to warrant its being tried on the testing machine. If the Microscope condemns the material, it is not worth while going to the expense of having it tested by more expensive methods. If the Microscope fails to reveal any flaw, then the material may be sent to the testing machine to be further proved. The larger the specimens that would be required for testing in the machine, the more marked

[*] Journ. of the Franklin Institute, cxiv. (1882) pp. 173-5.

the advantage of the Microscope in saving, in the case of specimens readily determined to be bad, the expense of further testing, and the risk of using it in construction. The samples shown this evening are of bridge timbers, and the lesson they are intended to convey is that had this method of examination been followed, the material which was proved to be faulty after being built into the bridge, would have been promptly thrown out. The samples shown were photographed by Mr. W. E. Partridge, of New York, a professional engineer who is an enthusiastic amateur photographer, and to whom I am indebted for the particulars concerning them.

The timber from which the poor specimens were taken came in the form of a chip broken off when a highway bridge was wrecked in 1879–80. The timber formed a portion of the sill of a draw-bridge, which consisted of two 12-inch sticks, lying one on the other. The turntable casting having been somewhat too small, this 24-inch timber had to support one of the A frames of the bridge at a distance of about twelve inches outside of the bed-plate. After a few days of service, while an empty truck was passing over, the strain became so great that the A frame sheared the 24-inch sill, wrecking the whole bridge. The timber was so exceedingly poor that upon mounting it on the Microscope the porous and weak nature of its structure was at once discovered. Its annular rings are something like three times the distance apart which would be found in a piece of thoroughly good wood of a similar character. The medullary rays are few in number and short in length, while in good wood they are of considerable length, and so numerous that the tangential sections appear like a series of tubes seen endwise, or a number of parallel chains. After once seeing and comparing two samples of wood it is very easy to recognize their characteristic features by the use of a pocket magnifying glass.

The trunks and limbs of exogenous trees are built up of concentric rings or layers of woody fibre, which are held together by radial plates, acting like the trenails of a wooden vessel, or the " bonds " in a brick or stone wall. The rings or layers representing successive years' growths, are composed of tubes, the interstices between which are also filled with cellulose. The slower the growth of a tree the thinner these yearly layers, and the denser and harder the wood, other things being equal. This is true as between one kind of tree and another, and also between different individuals of the same kind.

Not only is the closeness of the growth an indication of the hardness and strength of the timber, but the size, frequency, and regularity of distribution of the radial plates which bind the layers together may be taken as a very close illustration or sign of the character of the wood and its ability to resist strain, especially that from crushing stress.

The micro-photographs of the sections of good and bad timber show that in the strong specimens the concentric rings are close in texture and of light width ; and the radial plates frequent, wide, long, and thick, while in the poor material, the reverse characteristics are shown.

The lesson to be learned from these microphotographs is that having proper views of transverse and radial lengthwise sections, and of sections perpendicular to a radius, of a standard piece of timber resisting certain standard or minimum strains, all timber having fewer rings per inch of tree diameter, fewer fibres, and fewer and shorter radial plates per square inch of section, should be rejected as not up to the standard, and applied for other purposes or used with a greater factor of safety.

This method has the advantage of enabling every stick of timber in a bridge to be inspected and judged, and is offered as an interesting and valuable aid to the breaking tests made by the machine.

In this connection I may offer as the parallel in metal-work two portions of pure Lake copper, one an ingot as ordinarily found, in which the grain is coarse and crystalline, the colour dark red, and the mass full of blow-holes; this is an average sample of copper casting. The other is run from the same pig, at the same heat, and in a similar mould, but with proper precautions to prevent oxidization; in consequence, there are no blow-holes, the grain is close and fine like that of the best bronzes, and the colour is salmon, which is the true copper colour. The "deoxidized" casting weighs 25 per cent. more than the ordinary casting from the same pattern, calipering the same. For these I am indebted to the Philadelphia Smelting Works, Twelfth and Noble Streets.

Tests made of the deoxidized copper rolled into sheets ·035 inch thick showed on strips 2 inches wide a tensile strain of 33,760 lbs. per square inch, ordinary fine copper in sheets being quoted by Trautwine at 30,000 lbs. This would show 12·5 per cent. superiority in the metal having the fine fracture. No. 20 "deoxidized" wire shows a calculated tensile strength of 45,000 lbs. per square inch, and still later tests of wire of the same thickness showed a calculated tensile strain of 41,056 lbs. per square inch for the ordinary, and 47,552 lbs. for the deoxidized, a striking confirmation of the indications of the Microscope."

The Microscope in Metallurgy.—A paper on this subject by M. Atwood was recently read before the San Francisco Microscopical Society.

In a former paper on "The Microscope in Geology," the author remarked that the Microscope in mining would soon become as important an instrument in guiding the miner in his operations as the compass was to the navigator, as only by the aid of the Microscope could be correctly determined what was so necessary for him to know, namely, the true character of the inclosing rocks of the different metalliferous veins he was either prospecting or working, and thereby rendering mining a less hazardous undertaking, and not allow the art to degenerate into a mere "trial-all" system. We are now only beginning, in the author's view, to understand and realize the great value of the Microscope in metallurgy. One of its most important uses, however, and to which he more especially calls attention, is in the milling of gold quartz, where it has aided in distinguishing and proving in the most unmistakable manner the true condition of the

gold in iron pyrites, which we now know to exist in a metallic state, being therefore only mechanically mixed with the iron pyrites, so that the amalgamation of the gold in the raw ore can be easily effected, and with little loss, if ordinary precautions are taken to have the ore reduced fine enough to liberate the gold enclosed in the finer particles of pyrites. Mr. Atwood procured samples of pyrites from most of the mining counties of this State, and made a careful microscopical examination of them, the result confirming in every respect the conclusions of Daintree and Latta published in Australia in 1874.

The paper was illustrated with several mounted specimens. One slide showed the gold on a crystal of pyrites, which, with the aid of an inch objective, was seen as a beautiful gilding on some of the planes of cleavage. Another slide showed the gold in little drops, also filling some of the small cavities. Still another showed the gold in little specks, imbedded in the pyrites. Another specimen disclosed the gold in fine specks or scales mixed with the sesquioxide of iron. Mr. Atwood has found that in the examination of all metals good bright daylight should, if possible, be used. The specimens, as seen by lamplight, did not exhibit the gilding as well as it was seen in the daytime.

Micro-Chemical Methods for Mineral Analysis.[*]—T. H. Behrens publishes a very full paper on this subject, commencing with an historical account of the origin and progress of micro-mineralogical methods, and with a detailed description of his " new micro-chemical method."

If, he says, the number of micro-chemical reactions which are at the disposal of the microscopist in the subject of petrography is much smaller, and their application is much more limited than in the microscopical anatomy of plant and animal tissues, the reason is certainly not that less advantage may be expected from the examination of the rocks by such methods. If in felspar the potassium and calcium could be detected with the same ease and certainty and their quantity appropriately ascertained, as is done in the case of starch by means of iodine, and of cellulose by means of iodine and sulphuric acid, how much petrography would be advanced by such a method of examination will be evident to most microscopists.

Endeavours were early made to extend the means of determining the constituents of rocks. Zirkel first examined his rock sections in ordinary light, then in polarized light, and in 1868–70 he introduced hydrochloric acid as a reagent to distinguish between decomposable and undecomposable minerals in basalt, viz. labrador from oligoclase and magnetite from titanic iron. Since then this acid has had its use extended, but only in a few cases were the products of the reaction subjected to examination, thus the formation of carbonic acid, of sodium chloride and of gelatinous silica, capable of taking up colouring matters, were used to demonstrate the presence of calcite, nepheline and decomposable silicates as olivine, chlorite, &c., respectively. Other micro-chemical reactions are the detection of apatite by a nitric acid

* Versl. en Mededeel. K. Akad. Wetensch, xvii. (1881) pp. 27–73 (1 pl.).

solution of ammonium molybdate, of the minerals of the hauyn group by means of sulphur vapour, and of opal by means of a magenta solution.

In the meanwhile the methods of optical examination were being greatly improved; the use of gypsum and quartz plates for increasing the double refraction, determining the depolarizing directions, and distinguishing between positive and negative double refraction, were borrowed in a complete form from the accessories of zoologists and botanists; through Tschermak the test of dichroism was applied (1869), and through Descloizeaux the stauroscope of Von Kobell was added (1875). The now tolerably complete instrumental methods were united by Rosenbusch in a convenient form (1876), and rapidly made known by his treatise on the whole subject. New cutting and polishing machines, Microscopes, and accessories were afterwards introduced, and principally from the workshops of Fuess, in Berlin, and Seibert, in Wetzlar. The advantages of the purely optical method of examination are that with a compact apparatus and without any damage to the preparation, it can be examined and determined quickly, and in comparison, simply, in a way impossible with hand specimens. The physical properties at first relied on for the discrimination of minerals, and then replaced by Werner and Mohs for the chemical properties, have again, although under altered conditions, become of primary importance in modern micro-mineralogy and micro-petrography. Unevenness of the faces and partial opacity ("milkiness, muddiness"), which interfere so greatly with the use of the goniometer, polariscope, and stauroscope, are removed by the use of thin sections, or nearly so; cleavage directions, which otherwise have to be sought for with a hammer and chisel, are at once detected; crystal enclosures can only be completely studied under the Microscope, and their constant occurrence in certain mineral species affords a new means of detecting such species, i. e. hauyn, noseau, leucite, quartz, garnet, &c. The success obtained by clever observers by these methods during the last fifteen years has been such as to place on a new basis the study of rocks, but even in these methods much practice is necessary, while in not a few cases, especially where decomposition has set in, in spite of all endeavours deductions can only be regarded with uncertainty.

The method of acting on a rock powder with hydrochloric acid, and examining before and after treatment mounted in balsam, is not a very successful one. The solution of the soluble part can indeed be filtered off and chemically examined, but the uncertainties still remain considerable. E. Bořicky was the first to make known a connected system of micro-chemical reactions, he excludes filtration, and his method is simple. It depends on the action of hydrofluosilicic, or of hydrofluoric acid on small fragments of the mineral or on the rock section itself, the separation of crystalline silicofluorides by evaporation, and the recognition of the several compounds by their form under a magnifying power of 200–400 diams.

But though the method is capable of rendering service in some cases, yet in others it is very insufficient, and there are considerable

difficulties connected with it. Examples of these difficulties are :—
the time required for the reaction, the formation of gelatinous pulver-
ulent white crusts of aluminium silicofluorides which hide the minute
crystals of the other silicofluorides, especially the very transparent
sodium salt, and then the calcium, iron, magnesium, and other
fluosilicates are very soluble, and crystallize only when the solution
dries up completely. Owing to these difficulties, and the want of
methods for detecting silica and alumina, the author was led to look
for other methods more convenient, quicker, and having a wider
application.

Preparation of the Test Sample.—If the individuals composing the
rock are larger than 1·5 mm., then small fragments may be broken
from splinters of the rock by means of a pair of pliers ; their homo-
geneous nature is tested by a lens, or a low power under the Micro-
scope. If the rock is of a finer grain it must be crushed and the
dust removed ; using a low power small fragments of any of the
constituents may now be picked out for examination. If the con-
stituents are such as not to be readily distinguished from each other,
when coarsely powdered, a section must be made of the rock, but no
thinner than is necessary to give sufficient transparency for examina-
tion under a magnifying power of a hundred diameters ; the top surface
of the section may be either slightly polished or smeared with
glycerine or oil. The balsam is softened by a gentle heat, and the
required fragments picked out under the Microscope with a needle or
knife, using a low power and a high eye-piece, and freed by ignition
from balsam, &c. The selected fragments are ground in an agate
mortar. They are brought into solution by means of a very little
fuming hydrofluoric acid, or of ammonium fluoride and strong hydro-
chloric acid (this is done in a small platinum spoon) and then gently
evaporated to dryness ; the residue is moistened with a small quantity
of dilute sulphuric acid and heated till most of the free sulphuric
acid is removed. Water is then added, and the whole gently boiled
until but little more than one drop remains. This solution of the
sulphates is taken up by a capillary glass tube of 0·2 mm. diam.,
and in this manner divided and placed on slides for examination by
the tests for the various substances. The solutions are examined
without cover-glass, since it allows of better and quicker working ;
the objective is protected by a small plate of mica fastened on with a
drop of glycerine, a power of 150–250 diams. is most convenient.
The weight of substance required is from 0·2 to 0·5 milligram.

Calcium.—If any considerable quantity is present gypsum begins
to crystallize out at once in short prisms, or if in smaller quantity
then after a few minutes as crystals of the usual form of gypsum,
∞ P. P. ∞ P. ∞ P. ∞ ∞ . Mean size 0·060 mm. If but a trace of
calcium is present it may be detected by allowing the drop to absorb
a little alcohol vapour, the gypsum then separates in needles.

Potassium.—To the preceding test-drop is added a drop of platinum
chloride solution, by means of a loop of platinum wire. The double
salt soon separates ; if not, it may be accelerated by the action of
alcohol vapour. It forms very sharp light-yellow octahedrons, with

a high refractive index. Size 0·010–0·030 mm. The separation of the silico-fluoride is not so rapid, nor are the crystals nearly so easily recognized. The phosphomolybdate greatly resembles in colour and form the platinum double salt, but separates very much more slowly. Cerium sulphate quickly produces a precipitate of a double salt (see under Sodium).

Sodium.—The reagent used is a concentrated solution of cerium sulphate. If much sodium is expected place near the test-drop one of the reagent, and connect them by a small thread of glass, the latter drop then becomes turbid and under a power of 600 diameters is seen to contain whitish, translucent particles of scarcely 0·002 mm., and if potassium were present also larger spheroids greatly resembling potato starch, size 0·005–0·008 mm. If less than 1 per cent. of alkaline sulphate is supposed to be present, the two drops are at once allowed to touch each other, and the potassium salt forms in lumps, or occasionally in truncated rhombs, six or eight-sided, while the sodium salt forms short pointed prisms, like the Navicellia, size 0·003–0·005 mm. These are not to be confounded with crystals of the cerium sulphate itself, which have the same form, but are five or six times the size. Any great excess of sulphuric acid must be avoided. The separation of the sodium silico-fluoride is not so delicate (see under Fluorine).

Lithium.—After precipitating any lime present as gypsum, the lithium is thrown down by addition of an alkaline carbonate. The monoclinic crystals resemble those of gypsum, but are yet quite distinguishable, size 0·050–0·075 mm.; they are moreover distinguished by their solubility in dilute sulphuric acid. Crystalline magnesium double carbonates can only be formed if a large excess of alkaline carbonate is employed. Phosphoric acid may entirely prevent this test for lithium.

Barium and Strontium.—These exist as sulphates in the insoluble residue left in the platinum spoon. The residue is heated with concentrated sulphuric acid, and the solution brought by a capillary pipette on to a slide. On cooling and absorbing water the crystalline sulphates separate. Barium sulphate forms small crossed lens-shaped crystals, size 0·005–0·012 mm. Strontium sulphate separates after the barium salt, the crystals likewise form crosses, but are distinguished by their greater complexity and size, viz. 0·020–0·045 mm. If much calcium is present in the mineral, gypsum crystals will be formed, they appear last of all, and in their usual forms. Lead would also appear here, the crystals have the same size as those of barium sulphate, but the form of strontium sulphate.

Magnesium.—To the test-drop is added a little ammonium chloride and ammonia until alkaline, and left a minute or two for any iron and manganese present to oxidize. At one cm. from this drop is placed a drop of water containing a fragment of microcosmic salt, the two drops are connected by a thread or two of glass. The crystals are very characteristic, being hemimorphous, if formed quickly peculiar skeleton growths of 0·060 mm. result, but if formed slowly only well-defined crystals of 0·010–0·020 mm.

Aluminium.—After long searching a very satisfactory reagent was found in cæsium chloride. A platinum wire is dipped into the concentrated solution, and the test-drop stirred with it, brilliant octahedrons of cæsium alum rapidly form, varying in size from 0·035 to 0·090 mm. The presence of iron has no effect.

Iron and Manganese can be so easily detected by ordinary methods that no special microscopic method is required.

Sulphur requires to be converted into an alkaline sulphate; sulphides are fused with nitre and sodium carbonate, insoluble sulphates with sodium carbonate. The coarsely powdered fusion is put in a drop of water; near it is placed a drop containing aluminium chloride, hydrochloric acid, and cæsium chloride; on connecting the two drops with a thread of glass the formation of cæsium alum shows the presence of sulphur.

Phosphorus and Arsenic.—These are brought into a soluble form by fusion with sodium carbonate, or with addition of nitre if arsenides may be present. A concentrated solution of ammonium chloride is added to the test-drop, and close by side of this is a drop of water containing a particle of magnesium sulphate (see further under Magnesium). The ammonium magnesium phosphate is not to be distinguished in form from the arsenate; addition of silver nitrate or of sulphuretted hydrogen affords no satisfactory distinguishing test. If it is required to test for both, the substance is to be fused with cyanide of potassium and carbonate of sodium in a narrow tube, the arsenic sublimes as metal and the residue containing only the phosphorus is tested as above. The test with ammonium molybdate solution is less satisfactory than that with magnesium sulphate.

Chlorine cannot be detected by silver nitrate, as the precipitate under the Microscope has no characteristic appearance. Mercurous or lead nitrate are more suitable, but have disadvantages; thallium sulphate is the best reagent. The test is heated with an excess of sulphuric acid in the platinum spoon and the hydrochloric acid gas evolved collected in a small drop of water hanging to a coverglass, which is cooled by a larger drop of water on the top, and lies on the platinum spoon. The top drop of water is removed, the glass turned over and laid on a slide, and into the test drop is put a particle of thallium sulphate. The crystals of thallium chloride formed by any of these means are octahedrons with rhombic dodecahedrons, with a very strong refractive index, size 0·010–0·015 mm. The crystals are often grouped together in threes or fours, and then reach to 0·050–0·100 mm. Bromide of thallium is scarcely to be distinguished from the chloride, but the crystals of the iodide are distinguishable by their smallness, the largest rosettes measuring 0·020 mm., and by their intense yellow colour in reflected light; the fluoride is more soluble, has a somewhat different form, but appears very transparent and pale compared with the chloride.

Fluorine.—The test is first fused with soda—and silica if necessary—and then after addition of acetic acid evaporated to dryness; the residue is moistened with sulphuric acid and gently heated, the platinum spoon being covered with a concave lid of platinum foil, the

convex under side holding a drop of dilute sulphuric acid, the top some drops of cold water; after the reaction the cooling water is removed and the underneath drop put upon a varnished glass or a polished plate of barytes. Into the test-drop is put a little sodium chloride, beautiful six-rayed rosettes of 0·1 mm. form, then hexagonal plates and prisms with pyramids.

Silicon and Boron.—The following method allows of these two, i. e. supposing both to be present, to be separated and detected. The test is treated in the platinum spoon with a mixture of sulphuric and hydrofluoric acids, and heated very gently, silicon fluoride alone volatilizes and is collected and tested as under Fluorine. After addition of more hydrofluoric acid the heating is repeated but until fumes of sulphuric acid escape. The drop on the platinum cover is then evaporated to dryness at about 120°, the residue moistened after a minute or two with a drop of water, the solution brought on to a varnished glass, and a little potassium chloride added; potassium borofluoride separates in acute plates and rhombs, whose diameters are as 2 : 3, size 0·030–0·050 mm., the obtuse angles are sometimes replaced by edges. If no crystals separate at first, it is necessary for the drop to evaporate to dryness before making a conclusion.

Water is tested for by heating in a capillary tube as usual, with due precautions. The delicacy of the reaction may be increased by bringing into the tube a very little of the residue left by evaporating an alcoholic solution of magenta on glass; these thin skins are opaque and have a beetle-green lustre, on becoming moist they appear transparent and red.

The author is still occupied with finding suitable tests for some of the rarer elements, and with the more difficult task of finding reactions capable of being carried out on the rock section itself. A dozen examples are given of the applicability of the above methods; thus in 0·2 mgr. of sodalite were detected aluminium, calcium, potassium, and sodium, and in 0·1 mgr., chlorine; in 0·2 mgr. axinite were detected silicum, boron, aluminium, magnesium, and calcium; and in 0·3 mgr. apophyllite containing 1 per cent. fluorine, the latter was detected.

Microscopical Characters of Hailstones.[*]—A hailstorm at Innsbruck in September 1881, afforded J. Blaas an opportunity of examining the hailstones and determining the following results amongst others.

The opaque white layers which occurred in alternation with transparent ones and showed the appearance of radiating structure owing to the radial arrangement of the air-bubbles, never afforded any evidence that the crystalline elements were radiating in their arrangement; on the contrary, they were seen by the use of polarized light to consist of granules of ice, quite irregular in shape. The enclosed air-bubbles, some of which were of the smallest possible dimensions, had very irregular lobate forms, which always showed a

[*] Bote f. Tirol u. Vorarlberg, 1881, No. 215. Cf. Naturforscher, xiv. (1881) p. 454.

tendency to radiating arrangement. Among the substances inclosed were certain vacuolated masses, exactly similar to the drops of liquid found in crystals; they were very small, the vacuoles being very wide with dark margins. No movement was ever observed in the latter, but an argument in favour of their liquid nature is that as soon as (by melting) they are at the margin of the section of hailstone, they suddenly become empty, while the surrounding ice persists for a time. The exact nature of the other dirty and dust-like masses inclosed, which were by no means scarce, could not be determined.

Appearances presented by Air-bubbles and Fat-globules in White and Monochromatic Light.—We extract from Professor Ranvier's work on Histology,[*] the figures which illustrate the appearance at various points of the focus of an air-bubble in water and Canada balsam, and of a fat-globule in water, a diaphragm of about $\frac{2}{3}$ of a mm. being placed at a distance of 5 mm. beneath the stage, and the concave mirror exactly centered.

Air-bubbles in water.—Fig. 142, No. 1, represents the different appearances of an air-bubble in water. On focussing the objective to the middle of the bubble (B), the centre of the image is seen to be very bright, brighter than the rest of the field. It is surrounded by a greyish zone, and a somewhat broad black ring interrupted by one or more brighter circles. Round the black ring are again one or more concentric circles (of diffraction) brighter than the field.

On focussing to the bottom of the bubble (A), the central white circle diminishes and becomes brighter, its margin is sharper, and it is surrounded by a very broad black ring, which has on its periphery one or more diffraction circles.

When the objective is focussed to the upper surface of the bubble (C) the central circle increases in size, and is surrounded by a greater or less number of rings of various shades of grey, around which is again found a black ring, but narrower than those in the previous positions of the objective (A and B). The outer circles of diffraction are also much more numerous.

Professor Ranvier explains these appearances by reference to Fig. 143, which is a sectional view of an air-bubble (in water) receiving upon its base a series of parallel rays. The rays which passes through the centre of the bubble (undergoing no deviation) and those at a, a', a'' (which are more or less deflected by refraction) reach the eye of the observer, whilst a''' being incident at the limiting angle for rays which pass from water to air (48° 35′) is totally reflected, and does not reach the eye. The same is the case with the rays beyond a''', so that the margin of the bubble has a dark zone, varying as in Fig. 142, No. 1, A, B, C, according as the objective is focussed to the lower, central, or upper parts.

Air-bubbles in Canada Balsam.—Canada balsam being of a higher refractive index than water, the limiting angle instead of being 48° 35′ is 41° only, so that rays which are incident much less obliquely on the surface of separation undergo total reflection, and it will be

* Traité technique d'Histologie, 1878, pp. 14–20 (4 figs.).

only those rays which fall very close to the lower pole of the bubble
that will reach the eye, and the black marginal zone will therefore be
much larger.

Fig. 142.
This is shown in Fig. 142, No. 2.   When the objective is focussed
to the bottom of the bubble (A'), we have a small central circle,
brighter than the rest of the field, all the rest of the bubble being
black, with the exception of some peripheral diffraction rings.   On
focussing to the centre (B') or upper part (C') of the bubble, we have
substantially the same appearances as in B and C, with the exception
of the smaller size of the central circle.

    Fat-globules in water (Fig. 142, No. 3).—These illustrate the case
of a highly refracting body in a medium of less refractive power.

    When the objective is adjusted to the bottom of the globule A'',
it appears as a grey disk a little darker than the field, and separated
from the rest of the field by a darkish ring.

    Focussing to the middle of the bubble (B''), the central disk
becomes somewhat brighter, and is surrounded by a narrow black ring,
bordered within and without by diffraction circles.

On further removing the objective the dark ring increases in size, and when the upper part of the objective is in focus, we have (C″) a small white central disk, brighter than the rest of the field, and sharply limited by a broad dark ring which is blacker towards the centre.

FIG. 143.
These appearances are the converse of those presented by the air-bubble. That, as we saw, has a black ring and a white centre, which are the sharper as the objective is approached to the lower pole of the bubble. The fat-globule has, however, a dark ring which is the broader, and a centre which is the sharper, according as the objective is brought nearer to the upper pole.

These considerations, apart from their enabling us to distinguish between air-bubbles and fat-globules, and preventing their being confounded with the histological elements, enable two general principles to be established, viz.—Bodies which are of greater refractive power than the surrounding medium, have a white centre which is sharper and smaller, and a black ring which is larger when the objective is withdrawn, whilst those which are of less refractive power have a centre which is whiter and smaller, and a black ring which is broader and darker when the objective is lowered.
FIG. 144.   FIG. 145.

Monochromatic Light.—The same phenomena are observed by yellow monochromatic light, except that the diffraction fringes are more distinct, further apart, and in greater numbers than with ordinary light. A fat-globule, indeed, seems to be composed of a series of concentric layers like a grain of starch. With blue light these fringes are also multiplied but are closer together and finer, so that they are not so easily visible. Yellow monochromatic light, therefore, constitutes a good means for determining whether the striæ seen on an object are peculiar to it, or are only diffraction lines. In the former case they are not exaggerated by monochromatic light, but if, on the contrary, they are found to be doubled, or quadrupled, with this light, we may be certain that they are diffraction fringes.

Figs. 144 and 145 show the appearance of air-bubbles in water, when illuminated by yellow and blue monochromatic light.

ROYAL MICROSCOPICAL SOCIETY.

COUNCIL.
ELECTED 8th FEBRUARY, 1882.

PRESIDENT.

PROF. P. MARTIN DUNCAN, M.B., F.R.S.

VICE-PRESIDENTS.

ROBERT BRAITHWAITE, Esq., M.D., M.R.C.S., F.L.S.
ROBERT HUDSON, Esq., F.R.S., F.L.S.
JOHN WARE STEPHENSON, Esq., F.R.A.S.

TREASURER.

LIONEL S. BEALE, Esq., M.B., F.R.C.P., F.R.S.

SECRETARIES.

CHARLES STEWART, Esq., M.R.C.S., F.L.S.
FRANK CRISP, Esq., LL.B., B.A., V.P. & TREAS. L.S.

Twelve other MEMBERS of COUNCIL.

LUDWIG DREYFUS, Esq.
CHARLES JAMES FOX, Esq.
JAMES GLAISHER, Esq., F.R.S., F.R.A.S.
J. WILLIAM GROVES, Esq.
A. DE SOUZA GUIMARAENS, Esq.
JOHN E. INGPEN, Esq.
JOHN MAYALL, Esq., Jun.
ALBERT D. MICHAEL, Esq., F.L.S.
JOHN MILLAR, Esq., L.R.C.P.Edin., F.L.S.
WILLIAM THOMAS SUFFOLK, Esq.
FREDERICK H. WARD, Esq., M.R.C.S.
T. CHARTERS WHITE, Esq., M.R.C.S., F.L.S.

I. Numerical Aperture Table.

The "APERTURE" of an optical instrument indicates its greater or less capacity for receiving rays from the object and transmitting them to the image, and the aperture of a Microscope objective is therefore determined by the ratio between its focal length and the diameter of the emergent pencil at the plane of its emergence—that is, the utilized diameter of a single-lens objective or of the back lens of a compound objective.

This ratio is expressed for all media and in all cases by $n \sin u$, n being the refractive index of the medium and u the semi-angle of aperture. The value of $n \sin u$ for any particular case is the "*numerical aperture*" of the objective.

Diameters of the Back Lenses of various Dry and Immersion Objectives of the same Power (¼ in.) from 0·50 to 1·52 N. A.	Numerical Aperture. ($n \sin u = a$.)	Angle of Aperture (= 2 u).			Illuminating Power. (a^2.)	Theoretical Resolving Power, in Lines to an Inch. ($\lambda = 0.5269\,\mu$ = line E.)	Penetrating Power. ($\frac{1}{a}$)
		Dry Objectives. ($n = 1$.)	Water-Immersion Objectives. ($n = 1.33$.)	Homogeneous-Immersion Objectives. ($n = 1.52$.)

	0·50	60° 0'	44° 10'	38° 24'	·250	48,200	2·000

EXAMPLE.—The apertures of four objectives, two of which are dry, one water-immersion, and one oil-immersion, would be compared on the *angular* aperture view as follows:—106° (air), 157° (air), 142° (water), 130° (oil). Their actual apertures are, however, as ·80 ·98 1·26 1·38 or their numerical apertures.

THE "SOCIETY" STANDARD SCREW.

The Council have made arrangements for a further supply of Gauges and Screw-tools for the "SOCIETY" STANDARD SCREW for OBJECTIVES.

The price of the set (consisting of Gauge and pair of Screw-tools) is 12s. 6d. (post free 12s. 10d.). Applications for sets should be made to the Assistant-Secretary.

For an explanation of the intended use of the gauge, see Journal of the Society, I. (1881) pp. 548-9.

ADVERTISEMENTS FOR THE JOURNAL.

Mr. CHARLES BLENCOWE, of 75, Chancery Lane, W.C., is the authorized Agent and Collector for Advertising Accounts on behalf of the Society.

Organisms from excrement of Goat & Goose.

TRANSACTIONS OF THE SOCIETY.

XV.—*On some Organisms found in the Excrement of the Domestic Goat and the Goose.*

By R. L. Maddox, M.D., Hon. F.R.M.S.

(*Read 8th November*, 1882.)

Plate VII.

When studying lately the appearances of the hay-bacillus, both in the fresh and putrid infusion of hay, it occurred to me that it would be worth while to examine the excrement of a herbivorous animal, and a grass-feeding bird. Accordingly, I procured the fresh excreta of the goat, and of the goose, taking from the latter only the part but little, if at all, contaminated with urates. The examinations were begun in the month of August last, and as they proved rather interesting, and may open up a study that may furnish results for experiment, I venture briefly to offer a few remarks upon the organisms found. Photomicrographs were made of some of these, by a Seibert's $\frac{1}{16}$ water-immersion objective, without collar adjustment, kindly lent to me by Mr. Curties for this purpose. I may remark that the objective answered well with the

---

EXPLANATION OF PLATE VII.

(Lithographed from some of the Photomicrographs exhibited.)

Fig. 1.—A few of the free and growing spores found in the mixture of the goose excrement.

„ 2.—Part of the layer immediately beneath the upper layer, containing micrococci, in the mixture of the goose excrement.

„ 3.—Part of the felted mass of short rods, and part of some long free filamentary chains. These appeared later in the same mixture.

„ 4.—The earliest notice of *Spirillum* in the goat excrement.

„ 5.—Shows the marked increase in the number of *Spirilla*, and the diminution in the number of the rods.

„ 6.—*Spirillum* from goat excrement. [The original photomicrograph was taken with the addition of a Zeiss amplifier, and magnified to 651 diameters; the others, each, to 365 diameters.]

camera extended to a certain length, and also when used with a Zeiss amplifier at the same extension; but at distances much beyond, the want of the collar adjustment became rather apparent; hence the enlargement of the objects was chiefly kept within very moderate dimensions, yet sufficient for illustration. I may add, that I believe they are within easy reach of the engraver's power, which apparently was not the case with the photographs of the minute organisms found in rainwater-ice and hail, described in a previous paper.*

The examination was proceeded with in the following manner: a portion of fresh excrement of the goat was broken up with a clean glass rod in some freshly distilled water, and immediately covered with a glass plate. Examined by the Microscope at the time, numerous bacteria of various sizes, and a very few rods of, apparently, hay-bacillus were present, besides large quantities of partially digested vegetable matter suspended in a somewhat glutinous material, most likely mucus from the intestinal canal. The mixture was set aside in the room without artificial heat, the ordinary temperature ranging between 60° and 70° F., and fully exposed to daylight. On the third day when examined there was a thin scum extending over a large part of the surface. This scum contained numerous bacteria, some small rods, and here and there in the thinner parts of the pellicle some bright oval bodies with sharp outlines, whilst free from the scum were many larger and longer rods, both straight, and with a well-marked wide curvature, not angular; these rods were in active movement; there were also a few spores with outgrowths, these had the spore ends nearly globular, and the outgrowth or extension very pale and slightly granular, with a *gentle curve*. These spores had a slight forward and backward movement, also a peculiar swaying motion from side to side, the spore end forming the fulcrum. I believe these must be regarded as the spores of the *Spirillum*, which appeared later. A portion of the upper part of the fluid was removed, and freshly distilled and reboiled water added both to it, and to replace the quantity removed from the original portion. Both vessels, being covered, were placed in a dark box, and kept at a pretty constant temperature of 90° F. for twelve hours, when a fresh examination was made. Both vessels now teemed with infusoria and bacteria, the fluids had become more or less ropy, especially the original one. The organisms in the diluted portion consisted chiefly of active rods of very variable lengths, many having the wide curvature. No spores were visible. The original portion which had been diluted was divided into three layers, the surface one being of a dark greenish-brown colour, the second very much paler, whilst the lowest consisted of the debris of the food.

* *Ante*, p. 449.

The rod organisms in the upper layer resembled those in the diluted portion, but were far more numerous, and in very active movement, the bend in the curved ones being used apparently as an axis for locomotion. The bacteria had very little motion, the fluid being most likely too slimy; no spores were visible at this stage.

Hay was steeped for twelve hours in cold water and the liquid sterilized by boiling; when cold, a portion was added to the original but diluted mixture and gently stirred, whilst another portion of the hay infusion was infected from the former. All three vessels were now left exposed to daylight and the ordinary temperature of the room for a couple of days. Re-examined, the long rods had almost disappeared in the hay infusion that had been infected, and chiefly very short rods could be found; bacteria and infusoria were also present.

In the mixture simply diluted with distilled water, the rods were now fewer and less active; a pellicle on the surface was crowded with motionless bacteria; the infusoria still abounded; there was no offensive smell. The original fluid, or mixture, now diluted with the hay infusion, was examined. It was densely crowded with straight and curved rods of very variable lengths, and a few spirilla were visible, some having only one-and-a-half turns, others two to six; these were in active movement. In Fig. 4 (Pl. VII.) is represented the first notice of *Spirillum* in the mixture. In different parts of the slide some single large micrococci and also smaller double ones were noticed. The infusoria still abounded, and the mixture had now a faint sickly odour. Attention was confined to this mixture. After another twenty-four hours the rods and spirilla appeared nearly equally abundant, some of the latter having as many as thirty-three angular turns. The curvatures, both in width and depth, differed considerably. These organisms continued about matched for four days, when the *Spirillum* got the upper hand, the number of rods lessening; this is fairly well shown in Fig. 5. The survival of the fittest was evidently taking place, but at the same time also appeared another organism contending for the mastery, viz. a very delicate mycelium spreading in every direction through the fluid, which quickly rendered all further observation useless. The fluid was, however, kept for five weeks, and at the end of that period the rods and spirilla had well nigh disappeared, and nothing could be found by which to determine to what object the mycelium belonged. The mycelium was in very long twisted threads not larger than the rods, and at first I fancied they might be the rods in their filament stage, but close examination soon showed this not to be the case, as the threads had short outgrowths at very variable distances.

In the excellent contribution upon the life-history of *Spirillum*

given by P. Geddes and J. Cossar Ewart, M.D., in the Proceedings of the Royal Society, No. 188, 1878, it is shown that at one term of existence, the screw-shaped rods become less twisted, and finally straight, passing into the ordinary rod form as in Fig. 7, given by them. They also suggest that the term *Vibrio* should not be considered as generic. When examining the above-named fluids I have repeatedly found many of the long spirilla motionless, with one half having lost all twist except a large gentle curve, but that end presented a very delicate pale, very finely granular condition, differing entirely from the other part, the end being scarcely visible even when stained, and I have regarded this as a progressive dissolution of the organism. In the case I have mentioned we might have expected the spirilla to have reverted to rods, which was not the case, so far as I could determine, and from the *Spirillum* found in the goat excrement, appearing after and so largely replacing the rods, I think it offers a fair plea that *Bacillus* and *Spirillum* are to be considered distinct, though the latter, when broken up, may greatly resemble bacillus rods. The straight rods I should regard as *Bacillus subtilis*, and the curved ones as merely an accidental variation in their form, though many with a single curvature had very much the appearance of *Vibrio rugula*.

In the same paper it is stated the parent or spore-bearing hyphæ are locomotive, "and the spores quiescent." The authors say, "The life-history of *Spirillum*, so far as we at present know, may be thus summarized. The well-known motile corkscrew may alternate between the active and resting states, and ultimately lengthen out into a small filament, which loses its definite twist, and may freely bend or straighten. This thread grows into a much larger and longer motionless filament in which spores appear. These rapidly divide and acquire a bright brown colour, the filament re-assuming the motile condition, and sooner or later breaking up."

The spiral organisms were rigid, with a spiral movement. In size they appear rather smaller than the figures given of *Spirillum volutans*, and larger than *Spirillum tenue*, approaching nearer to the *Vibrio serpens* of Cohn. If the term vibrio were put aside, would it not be as well to substitute for the curved forms of *Bacillus*, *Bacillus curvatus*, or *Bacillus subtilis* var. *curvatus*, and thus help to get rid of the objectionable term ? Having some doubt as to the exact species of *Spirillum*, I have not given more than the generic name.

I found the organisms varied so considerably according as they were left dry upon the cover-glass after or before staining, or mounted in distilled water, or in a semi-saturated solution of acetate of potash, or in dammar medium, that I have not given the measurement. The one method of mounting would not agree with the

others, as shown in some other photomicrographs, taken with the same objective, at the same distance from object to screen; but I have given the measurement of the $\frac{1}{1000}$ of an inch at the same distance.

The examination of the goose excrement, the part not covered with urates, was made by breaking up a portion in freshly distilled water with a clean glass rod, then covering it with a plate of glass, and setting it in the daylight at the ordinary temperature of the room, at the same time as the former experiment. Examined on the slide, chiefly vegetable debris of grass, coarse and fine granular organic and mineral matters, with here and there a bright point, like an ordinary bacillus spore, amongst various bacteria, and a very few short rods were noticed.

After twenty-four hours, a thin scum appeared in several places on the surface of the fluid, which had now settled into three layers, the heavy solid constituents having sunk to the bottom. The top one was of a dense brown colour, the middle much clearer and less coloured. After another twenty-four hours the top liquid was examined; being diluted with a droplet of water on the slide, it was seen to contain numerous very bright oval forms, many with outgrowths of varying lengths, evidently germinating spores, apparently of the hay-bacillus. These had motion forwards or backwards; but not the singular swaying movement from side to side from a fixed point. There were also a few short rods, micrococci, and bacteria present. These were photographed, Fig. 1. On the following day the short rods had notably increased in number, but they did not appear to grow in length; fewer spores in growth were visible. The pellicle on the surface had increased, the part exposed to the air consisting, so far as I could make out, of bacteria mingled with micrococci, whilst immediately beneath, the micrococci formed a layer in a delicate transparent medium. This layer is seen pretty distinctly in Fig. 2. In various parts of the pellicle on the slide, small masses of minute bodies, highly refractive and set in a glœa, larger than the spores of the hay-bacillus, were seen. I believe they belong to a *Bacillus* of larger dimensions, as I have many times noticed similar bodies in connection with a short chain of stout short rods, in other preparations. Continued examinations for many days revealed nothing further; the rods had not grown, and the entire fluid was becoming of a greenish colour throughout, but at last upon several slides the bacilli were seen in chains of some length and in nearly all attached to a felted mass of small rods, and rods lying free, but close to the mass, as depicted in Fig. 3. In the filamentary chain, the joints appeared to be passing into the spore condition in a few. The little mass of free rods were motionless and of rather paler appearance than the ordinary rods of hay-bacillus; the fluid was crowded with infusoria,

there were numerous bacteria, but not active to any extent. The fluid had become ropy, the dark colour had lessened, the odour had become disagreeable. An attempt was made to cultivate the organisms in fresh sterilized hay infusion, but it was unsuccessful.

The original fluid was now stirred up, and allowed to re-settle, still it yielded nothing of change that I could discover upon the examination of many slides. It was kept for more than a month when the fluid had a sour smell and acid reaction. To the latter I think we may attribute the want of growth of the rods generally; evidently the pabulum was not favourable; at this stage a few octahedra of oxalate of lime were seen. The results offered a great contrast to those of the excreta of the goat.

Possibly, by fractional cultivations in proper media, we might be able to arrive at a more perfect study of the different organisms, and test their physiological peculiarities or their pathological reactions, if any. We may, I think, however take for granted that the spores have resisted the entire digestive process in both cases, but whether they, or the spirilla, would prove detrimental to guinea pigs or mice, I must leave to the care of those armed with the necessary powers, in this country, for such studies.

XVI.—*A Further Improvement in the Groves-Williams Ether Freezing Microtome.* By J. W. Groves, F.R.M.S.

In the present volume of the Society's Journal, page 430, Fig. 83, is described and figured the method by which, at my suggestion, ether was adopted as the freezing agent to a Williams microtome,[*] the chief merit being that the used ether is capable of being conveyed away into the external air without the operator being exposed

Fig. 146.
to its fumes, as is the case in most ether freezing microtomes, while at the same time the advantages of the Williams instrument are retained.

* Cf. this Journal, i. (1881) pp. 697–9 (1 fig.).

On page 432, Fig. 84, is shown a so-called improvement, though one which is useless, inasmuch as the razor is incapable of being levelled, and therefore cannot be kept parallel with the slides on which it works, the result being that no sections with parallel surfaces, and therefore no *thin* sections, can be cut.

The present further modification, Fig. 146, has consequently been made by Mr. Swift, of Tottenham Court Road, at my request. The machine now resembles that last mentioned in having an iron bracket with spring tube to receive either of the four holders for material, Figs. 84–7, and a clamp below by which it may be fixed to a table; but differs from it in that it has the glass top and razor-frame of the original Williams microtome.

The new Microtome, therefore, consists of an iron bracket to the top of which is fixed a glass plate with central aperture. Through this passes the upper end of the apparatus for holding the material to be cut, either for freezing by ether as in Figs. 146 and 84, or by ice and salt, as in that known as Pritchard's, Fig. 85, or for material imbedded, Fig. 86, or for clamping a tree stem or other structure not requiring to be frozen or imbedded. Each of these is held below the top in a spring tube capable of being tightened by a screw, and the whole instrument can be fixed to a table by a clamp which forms the bottom of the bracket. The sections are cut by a razor held in a Williams triangular frame, which is levelled by means of two base screws, and lowered for each section by means of the apex screw.

When using the ether freezing apparatus with this microtome, material to the thickness of $\frac{3}{16}$ inch can be frozen in $1\frac{1}{2}$ minutes, and good successive sections cut as thin as can be obtained by any microtome. When the material is once frozen scarcely any ether is required to keep up the action, so that the cost of the ether is rather less than that of ice, methylated ether sp. gr. ·720 at 1*s.* 6*d.* a lb. being used.

SUMMARY

OF CURRENT RESEARCHES RELATING TO

ZOOLOGY AND BOTANY

(principally Invertebrata and Cryptogamia),

MICROSCOPY, &c.,

INCLUDING ORIGINAL COMMUNICATIONS FROM FELLOWS AND OTHERS.[*]

ZOOLOGY.

A. GENERAL, including Embryology and Histology of the Vertebrata.

Spermatogenesis in Mammalia.[†]—G. Renson finds that, when the testicular canaliculi of the rat are treated with osmic acid, the following sets of cells may be made out: (1) Large, rounded cells with large nuclei, the protoplasm containing a number of granulations —these are the seminiferous cells of Sertoli. (2) Multinuclear cysts provided with a variable (4–20) number of nuclei, and varying in form according to their stage of development. Frequently the nuclei are slightly elliptical, an appearance which appears to be the forerunner of their conversion into the heads of the spermatozoa; in such cysts there is a distinct differentiation of the protoplasm, which has become condensed and limited around each nucleus; so that, when completely developed, we have rather to do with aggregations of cells than with multinuclear protoplasmic masses. (3) There are also small rounded cells, the nucleus of which presents every stage in the development of the head of the spermatozoa; these, which, with Sertoli, the author calls nematoblasts, have, like their predecessors, a refractive corpuscle placed near the nucleus.

The whole series of changes may be thus expressed: a generation of spermatozoa is developed, and expelled into the lumen of the canaliculus; the seminiferous cells multiply to form a new generation of nematoblasts; germ-cells are developed from a peripheral protoplasmic plexus which takes on the characters and situation of the seminiferous cells; a new generation of germ-cells is developed in the outer portion of the canaliculus. The author has not been able to determine the origin of these germ-cells. The result of following

---

out the history of these bodies is to show that there is a regular replace-
ment of one generation of cells by another, and, owing to this, a second
may take the place of the one expelled.

Early Changes of the Chick.*—It is certainly to be desired, in
the nterests of embryological students, that the principal facts and
inferences relating to the chick's development could at length be
established beyond the reach of controversy. For, alike on historical,
practical, and scientific grounds, this accessible type seems likely to
maintain its place as the standard of comparison for the embryogeny
of the higher vertebrates, and especially for the study of their initial
phases. The rapidity, however, with which these phases succeed one
another, and the diverse changes which, within very short periods,
occur in different parts of the same organism, present difficulties of
observation so great that our most skilled experts have not yet been
able wholly to overcome them. Hence our best works, those of
Kölliker and Balfour, cannot be regarded as in all respects satisfactory.
Hoping to dispel some remaining doubts Dr. W. Wolff returns to this
familiar subject; his observations suggest a discussion and review of
certain opinions of his predecessors.

As regards cleavage there is not much to be said. Why, he asks,
should writers assert that it occurs more rapidly near the centre and
surface than in the deeper and outer parts of the germ? No one
has proved this. A uniform rate for the change in question being
assumed, it must be over sooner in the region where it began. The
formation of the subgerminal cavity is best explained if we compare
it to the cleavage-cavity of mammals. Since the yolk retracts before
it divides, secreting at the same time a fluid mass, so, with the
approximation of the cleavage-spheres, becoming successively smaller
firmer and more numerous, their intercellular fluid likewise accumu-
lates and in the chick is lodged within the cavity formed by the with-
drawal of the entire germ from the food-yolk below. No membrane
separates the nutrient yolk from the germ. The false appearance of
a membrane on the floor of the germinal cavity is produced artificially
by coagulation of a film of the fluid white yolk.

The margin of the hitherto lenticular germ becomes, in the lower
portion of the oviduct, thicker than its centre, the central cells
probably spreading themselves as the primitive outer lamina is
developed. This "ectoblastoderma" is polyderic. Its cells are more
easily stained than those of the rest of the germ. The under surface
of the outer layer, in contact with this residuum, is uneven; but
whether, once formed, it receives cells therefrom or has henceforth an
altogether independent increase is not certain. There are now, in
the still unincubated germ, two kinds of cells and two only, (a) those
of the ectoderm, distinguished by their position, form, and chemical
characters, and (b) the cells beneath them, which do not constitute a
lamina and are best termed collectively the "remnant of the cleavage-
elements." These residual cells, compacted peripherally, are but
loosely grouped about the middle of the germ, which, partly on this

* Arch. f. Mikr. Anat., xxi. (1882) pp. 45–64 (1 pl.).

account, partly in consequence of the development of the ectoderm, appears thinner than it really is. Some of them lie scattered in the germinal cavity; others rest on its floor.

The first consequence of incubation, apart from the increase of all the cells of the germ, is the transformation and union of its deepest residual cells to constitute the monoderic inner lamina or " endoblastoderma." This layer consists of cells no longer rounded but like those of an epithelium and flattened, save where they are rendered thick by their large nucleus, so that in sections they seem fusiform. The under surface of the whole germ is protected by the inner lamina, which therefore roofs in the germinal cavity and beyond the latter is in close contact with the white yolk. Whether this outer portion be first formed or the transformation of residual into endodermic cells proceed contrary-wise, from centre to circumference, has not been determined.

In a bird's-eye view of the germ at this stage are seen an area pellucida and an area opaca. The former is conterminous with the germinal cavity. The latter corresponds to the peripheric region of the germ, resting on the surface of the white yolk. Such a germ differs from a typical gastrula in that between its outer and inner laminæ are included cells not derived from either. These are the cells of the " middle-germ," or mesoblast.

Soon after the inner lamina can be distinguished, a dark spot shows itself, somewhat excentrically, in the clear area. This is the embryonal shield of von Baer. It is mainly due to a thickening of the outer lamina, and its appearance marks the development of the primitive streak, whose broadened cephalic border it represents. The primitive streak owes its origin to an invagination of a part of the outer lamina. The part so invaginated is cut off. But it soon ceases to form one whole clearly separable from the cells of the middle-germ, wherein it becomes implanted. For here cells are associated which have a twofold origin, ectodermic and mesoblastic. Hence many of the contradictions into which discordant observers have fallen. [It is a pity that time did not permit Dr. Wolff to study the remarkable conclusions of the late Prof. Balfour on this subject.*] The floor of the primitive streak, thus reinforced by a copious contribution of cells from the middle-germ, Dr. Wolff terms the " axial plate." As the germ continues to grow, the axial plate gives rise to the rudiment of the cerebro-spinal system, the primitive vertebræ with the lateral plates, and the chorda. The primitive groove and its boundaries are designated, in consequence, dorsal. Our author does not consider the medullary and primitive grooves as distinct formations, and denies the possibility of a displacement of one in front of the other. The peripheral portion of the axial plate extends into the opaque area. To this portion, chiefly, if not exclusively, derived from cells of the middle-germ, the phase " vascular lamina " may conveniently be applied.

The accumulation of cells from the middle-germ about the ectodermic rudiment of the primitive streak is contemporaneous with

* See Quart. Journ. Micr. Sci., xxii. (1882), p. 174, and this Journal, *ante*, p. 314.

(and results from) the disappearance of the peculiar marginal thick-
enings which the blastoderm, since losing its lenticular figure, has
hitherto presented. While the mesoblast coincided in extent with the
ectoderm, it most abounded in the hinder and outer regions of the germ,
being more sparingly manifest anteriorly and in the area pellucida.
But with the formation of the primitive streak a rapid centripetal
migration of the middle-germ ensues, and its cells retreat within the
limits of the clear area. Much confusion prevails as to the use of the
phrases—marginal protuberance, germinal wall and germinal protu-
berance. The "Keimwall" of His belongs to the white yolk. It is
identical with the "Keimwulst" of Kölliker, which, however, the
latter views as synonymous with the "Randwulst" of Goette. But
this lies wholly outside the white yolk, and is made up of the residual
cells between it and the outer lamina.

Remak first instituted the conception of germinal laminæ as at
present understood. [To a certain extent he was anticipated by
C. F. Wolff and von Baer.] He was tolerably right as to his facts,
but erred in his deductions. Unacquainted with the cleavage of the
hen's egg, he could not well appreciate its constitution before the
formation of the ectoderm, nor could he perceive the significance of
the germinal layers in the development of the higher animals
generally. He describes the germ of the unincubated egg as made
up of a firm outer and a more loosely constructed inner lamina.
From the latter, as a first result of incubation, his alimentary glan-
dular lamina separates by transformation of its cells. The residue of
the inner lamina is now the middle lamina. Apart from this deriva-
tion, at least nominally, of one germinal lamina from another, he
finally has at his disposal a middle and an outer lamina but not an
inner; since his first inner lamina is resolved into the middle and
the alimentary glandular lamina, which latter alone he deems the
earliest rudiment of a definite system of organs. Remak's interpre-
tation had many followers. They differ from him in words only who
derive a middle lamina from his inner lamina and give this name to
Remak's "Darmdrüsenblatt." It is all the same whether a splits
from b, or b from a.

This "Darmdrüsenblatt" is the inner lamina of Kölliker. What
remains of the germ constitutes the outer layer, in Kölliker's sense.
From it, therefore, he derives his middle lamina, which is formed by
the extension of masses of cells from the region of the primitive
streak, on both sides of the germ, between its ectoderm and endoderm.

Goette is right in describing a previous transfer of cells from the
marginal protuberance, centripetally. But this wandering does not
take place until after the formation of the inner layer. The
migrating elements are cells of the middle-germ, and together with
the cells of the primitive streak they make up the axial plate. The
inner germinal stratum of Goette, which divides into his inner and
middle laminæ, is equivalent to the first inner lamina of Remak, who
sometimes also designates this as the inner "Keimschicht."

Peremeschko, like Kölliker, is wrong in believing that in the
formation of the ectoderm and endoderm the whole substance of the

germ is used up. He derives his mesoderm from large spherical elements, described by him as cleavage-spheres, which wander from the floor of the germinal cavity into the space between the primitive layers. These elements, the megaspheres of His, are when first evident merely the residual cells of the germ; at a later stage they are aggregates of cells whose nuclei and borders have become inconspicuous through inception of yolk-granules. They are endowed with an extraordinary power of multiplication. The inner lamina, once formed, shuts off the rest of the germ from the germinal cavity, and by this time has received into itself the spheres in question, now for the most part resolved into their constituents, whose upward movement from the floor of the germinal cavity is due to their being specifically lighter than its contained fluid.

His resolves the germ of the new laid egg into one lamina, the outer, designating the residual cells collectively by the not well chosen name of subgerminal processes. After the formation of the inner lamina there appears in connection with the primitive streak what he justly enough terms the intermediate stratum. His does not derive all the connective tissues from this stratum, but imagines a migration of cells from the white yolk, out of which the vascular system is developed.

Until the appearance of the primitive streak the germ grows uniformly throughout. At its margin the outer and inner laminæ make together an acute angle, between the legs of which, as seen in sections, cells of the middle germ are packed. As soon as the primitive streak is formed, these cells back towards it and become involved in the constitution of the axial plate. Thereupon the margin, deprived of its intermediate cells, appears as a solid keel, with three or four tiers of cells only, exclusively made up of the ectoderm and endoderm. While this peripheral region continues to spread itself, the under cells separate from the upper, of which only a single tier now remains in continuity with the outer lamina. Some of the separated cells at once assume the features of the cells of the inner lamina (roofing the germinal cavity), as a prolongation of which they extend, beneath the outer layer, under the form of a thin membrane. This limiting membrane rests on the white yolk, but does not attain the extreme periphery of the germ. It there passes into an irregular mass composed of the other separated cells, which wander into the white yolk, become stellately branched, and anastomose to form a network whose meshes get filled with white yolk-spheres. Close to the margin of the germinal cavity, disappearance of the yolk-spheres changes this reticulum into a solid (polyderic) layer, passing gradually into the monoderic inner lamina. It can scarcely be doubted that all the cells between the outer lamina and the white yolk must be considered as representing the endoderm peripherally. The reception of granules from the white yolk may be termed a sort of primitive digestion. Subsequently, when the vascular lamina grows into the area opaca, it is separated from the white yolk by the limiting (endodermic) membrane, and its first formed vessels take up the nutrient fluid which through this membrane they receive. Cells,

however, are not thus transferred. The cellular elements detected by Goette on the floor of the germinal cavity, and thence seen to wander, at an early period, into the germinal wall, must not be referred to the white yolk itself. Certainly the latter contains cells, but these, as above shown, have come from the cleaved germ, to which they return. The white yolk has no direct share in the formation of the embryo.

It is well to be prepared with a definite answer to the question—what is a germinal layer? The cells constituting a primitive lamina must fulfil two conditions ;—they must arise directly from the germ, and possess their own peculiar properties. But two such laminæ can be demonstrated, the ectoderm and the endoderm. We should not reckon as primitive layers either (*a*) the aggregate of residual cells (inner pro-embryonic layer of Goette = first inner lamina of Remak) which lies beneath the ectoderm of the egg before incubation or (*b*) the mesoblast, which consists, when first formed, merely of undifferentiated cells of the germ, after its ectoderm and endoderm have separated. The admission of the middle-germ to the rank of a fundamental embryonic lamina renders impossible all attempts to settle the homologies of the primitive layers among the different classes of animals. But if we accept two primary layers only, this difficulty is removed at a stroke.

Thus, in like manner, may we classify the tissues from an embryonic point of view. They are either simple or compound. The simple tissues are ectodermic, endodermic or mesoblastic. The compound tissues are formed by the union of cells from the middle germ, or their derivates, with cells from the ectoderm or endoderm. This union is closer and takes place at an earlier stage of differentiation in the case of the striped muscle of vertebrate animals than with their cerebro-spinal system. We know that in some cœlenterates at least the muscular and nervous tissues are purely products of the ectoderm. There is still doubt as to the origin of many of the so-called endothelia.

Dimensions of Histological Elements.*—W. Krause gives a list (in 26 pp.) of the dimensions of the various histological elements, classified under different headings, such as Connective Tissue, Muscular System, Nervous System, &c.

"Nervous System" (e. g.) is subdivided into Nerve Tissue, Spinal Cord, Brain, Peripheral Nerve System, and Nerve Endings, and the 1st subdivision is dealt with thus :—

Nerve fibres, $0\cdot0018-0\cdot013$ (Krause), $0\cdot001-0\cdot02$ (Kölliker) thick.

Olfactory fibres, $0\cdot0038-0\cdot0068$ wide, $0\cdot0018$ thick. Nuclei, $0\cdot0068-0\cdot0113$ long (Frey).

Pale nerve-fibres, $0\cdot0017-0\cdot0027$ thick (Krause) ; (in Mammals) $0\cdot0033-0\cdot0056$ wide, $0\cdot0013$ thick ; Nuclei, $0\cdot006-0\cdot015$ long, $0\cdot0045-0\cdot0067$ wide (Kölliker).

Medullated nerve-fibres and *ganglion-cells* are dealt out in a similar way.

* Krause, W., 'Nachträge zum ersten Bande des Handbuches der Menschlichen Anatomie von C. F. T. Krause (3rd Aufl.).' 8vo, Hannover, 1881, pp. viii. and 170 (1 pl. and 81 figs.).

Influence of the External Medium on the Saline Constituents of the Blood of Aquatic Animals.[*]—L. Frédéricq points out that the water of the North Sea contains a little more than 3 per cent. of soluble salts, and has a marked salt and bitter taste; the blood of the Crustacea and Cephalopoda living in it has exactly the same taste, which leads to the supposition that it has the same chemical constitution; and this view is supported by chemical analyses. The blood of the crabs of the brackish water of Braeckman has a less salt taste, and that of the crayfishes of the Belgian rivers still less so. It would, then, seem to be certain that, in virtue of the laws of diffusion, there is a more or less perfect exchange of salts between the blood and the external medium, and the seat of this process is probably the gills. But this variation in chemical composition, according to the characters of the external medium, would appear to be confined to the " lower animals "; a similar diffusion might take place in fishes, but in them we find that the saline constituents of the blood are very different to those of the seas in which they live; an explanation of which may be found in the fact that the blood is in them much more isolated from the surrounding medium than it is in the invertebrate marine forms.

B. INVERTEBRATA.

Development of some Metazoa.[†]—In the third part of his studies on Comparative Embryology, E. Metschnikoff states that he finds that the identity between so called *Archigastrulæ* does not exist as Haeckel has supposed; nor must an *Archigastrula* be always bilaminate, for some very primitive forms contain mesodermal cells even during the blastula stage. Indications of a radial structure of the archigastrulæ have not been detected in the Echinodermata only; doubly symmetrical arrangements are not at first seen in the blastopore, and the elongated form of that structure must not, when found, be regarded as of palingenetic, but of adaptive origin. On the supposition that the radial gastrula form is the primary one, the question arises whether the gastrulæ of Echinoderms, and of such forms as *Lineus* and *Polygordius*, are really homologous; if they are so it would seem to be a necessary consequence that the anus of the Echinopædia is the homologue of the pharyngeal orifice of the worm—a comparison with which the author is apparently dissatisfied.

It is a question whether the Gastræa theory affords the promised key to the solution of morphological problems; the author points out that the formation of the endoderm, in many of the lowest Metazoa, by the appearance of separate cells in the segmentation cavity, can by no possibility be regarded as a compression of the process of invagination, though, on the other hand, the invagination seen in the higher Cœlenterata may quite easily be regarded as a shortened process. If we want to remain true to the Gastræa theory, we must suppose not

---

[*] Bull. R. Acad. Sci. Belg., iv. (1882) pp. 209–12.
[†] Zeitschr. f. wiss. Zool., xxxvii. (1882) pp. 286–313.

only that the head of the worm corresponds to the hinder end of the Echinoderm-larva, but that the mode of formation of the endoderm in the lower Metazoa has no phylogenetic significance. The so-called *Acœla* will have to be regarded as degenerate forms, though they are neither parasitic nor sessile. All these difficulties may, however, be overcome by the supposition that the *Gastrœa* does not represent the most primitive form of Metazoa, but a later stage which succeeded upon that of Metazoa without a digestive lumen, and with an internal digestive parenchyma. From this point of view the parenchymatous larvæ of sponges and hydroids, as well as the lowest accœlous Turbellaria, must be regarded as being closely allied to one another, and as representing the oldest Metazoa. It was not till later that there were developed from them animals with a differentiated enteric canal, like the hydroid polyps of the present day, where we see repeated the most important phylogenetic phases (migration of endodermal cells, formation of a solid parenchyma, and later development of an enteric lumen). The earlier development, in the course of time, of the endoderm may be compared to the early formation of such organs as the vertebrate notochord, and the change in time may well be allowed to have exercised a not unimportant influence in the process of gastrulation, and the large blastopores of some forms may be best ascribed to adaptive modification; to this also would appear to be due the appearance of several gastrula stages in the development of one and the same animal form.

In conclusion it is pointed out that, while in some cases we have this hypergastrulation, in others there are formed pseudo-gastrulæ, that is, stages similar, but not exactly corresponding to gastrulæ. Here may, perhaps, be ranged E. van Beneden's rabbit-gastrula, or his *Dicyema*, while an interesting example is to be found in the Cyclostomatous Polyzoa, the gastrulæ of Barrois being in fact preceded by a much earlier stage in which the endoderm is really formed. The author's notes on *Discoporella radiata* bring to an end a most suggestive essay.

Symbiosis of Dissimilar Organisms.*—G. Klebs here discusses symbiosis with mutual adaptation, which is generally represented by forms which are very widely separated, and often belong the one to the animal and the other to the vegetable kingdom. Instances are cited both among plants and animals; among the latter the corals are perhaps as remarkable as any, and here we frequently find that while the guest is dependent on the coral, the latter does not seem to require the guest; when, however, it is present, it may lead to very considerable modifications in the form of its partner. The specific characters of *Heteropsammia michelini* are to be referred directly to the presence of an *Aspidosiphon*.

Another set of relations is well shown by the case of the crab *Pagurus prideauxii* and the Actinian *Adamsia palliata;* when the former changes its shell, it seizes on the anemone by its chelæ and carries it off to its new home. The latter is completely adapted to

its mode of life, for it has two pedal lobes which become firmly attached around the orifice of the shell. The Actinian would appear to seize and strike smaller marine animals by its stinging cells, and these would thus come into the area of the sedentary crustacean. Like other writers on this subject at the present time, the author directs his notice to the yellow cells found in the Radiolaria.

Pelagic Fauna of Fresh-water Lakes.*—Professor F. A. Forel considers that Entomostraca alone show the peculiar character of pelagic animals, the pelagic fauna in its general features being similar in all the countries and lakes of Europe yet investigated, though seldom represented in any one lake by all the animals of the fauna.

The characters common to the animals of the pelagic region are due to their mode of life. They must swim incessantly, and therefore, instead of any organ of adhesion, they have a highly developed natatory apparatus ; they are sluggish, and escape their enemies by their nearly perfect transparency, which may be regarded as a mimicry acquired by natural selection, only those having held their own which are as transparent as the medium in which they live. They perform daily migrations, during the night swimming at the surface, and in the day descending into the depths.

As to the origin of the pelagic fauna, the author decides that certainly the palustrine or fluviatile Entomostraca have not become transformed in each lake into pelagic species or varieties. The almost complete identity of the European pelagic Entomostraca shows a common origin and distribution, and he believes that we must find the cause of the differentiation of the pelagic fauna in the combination of two different phenomena—the daily migrations of the Entomostraca, and the regular local winds of the great lakes. On the borders of great masses of water two winds prevail, one blows at night from the land to the water, the other by day from the water to the land. The nocturnal animals of the shore-region which swim at night at the surface are at this time driven towards the middle of the lake by the surface-current of the land wind, sink during the day (being driven away by the light into the deep water) and thus escape the surface-current of the lake-wind, which would otherwise have carried them again to the shore. Constantly driven further every night, they remain confined to the pelagic region, as they are not carried back again during the day. Thus a differentiation takes place by natural selection, until at last, after a certain number of generations, there remain only the wonderfully transparent and almost exclusively swimming animals which we know. When this differentiation has once taken place, the pelagic species is conveyed by the migratory water-birds from one country to another, and from one lake into another, where it reproduces its kind if the conditions of the existence of the medium are favourable. In this way we may find the pelagic Entomostraca in lakes which are too small to possess the alternation of winds, the animals having been differentiated by the action of the winds in other larger lakes.

* Biol. Centralbl., ii. (1882) pp. 299-305. Ann. and Mag. Nat. Hist., x. (1882) pp. 320-5.

In this way we can easily explain the differentiation of most pelagic species, with the exception of *Leptodora hyalina* and *Bythotrephes longimanus,* which are not related to the other fresh-water species, and for which we must, therefore, seek a *marine* origin. *Bythotrephes* would be derived from an ancestor which was common to it and to *Podon,* its nearest ally. *Leptodora,* on the contrary, according to Weismann's view, would have branched off from a primæval Daphnid, of whose direct descendants nothing further is known.

But how could the passage from salt to fresh water be effected? Pavesi supposes the closing of a fjord, and its gradual conversion into a fresh-water lake. This is possible; but for the definite decision of the question we have still no reliable materials. So soon, however, as the adaptation to fresh water had been effected, the distribution of these forms of marine origin took place in the same way as with other pelagic fresh-water forms, and thus these two forms would be introduced into lakes which were never in direct communication with the sea.

Professor H. N. Moseley also delivered an address * on "Pelagic Life" (Fauna and Flora), at the Southampton Meeting of the British Association, which constitutes a highly interesting summary of our existing knowledge on the subject.

Mollusca.

Curious Secretion in Gasteropods.—The parts termed salivary glands in prosobranchiate gasteropods are far from being sufficiently understood; they offer a tempting subject of research to young investigators. In particular is this the case with *Dolium galea,* the largest gasteropod of the Mediterranean. Poli was the first to notice the œsophageal organs of this mollusc. Keferstein has given an original description and figure of the whole apparatus in Bronn's ' Thier-reich.' Troschel noted the very acid " saliva" of *Dolium,* in which Boedecker found by analysis a large percentage of SO_4H_2. De Luca and Panceri confirmed his results, obtaining more than 3 per cent. of free sulphuric acid. They also observed that much carbonic acid was given off when the freshly excised " glands" were placed in contact with the air, and further showed that other prosobranchs, as well as *Aplysia,* likewise yielded free sulphuric acid. They especially indicated the enormous size of the "glands"; in a *Dolium* whose total weight was 1305 grammes, the shell weighed 550 and the " glands" 150 grammes. Hoppe-Seyler remarks that a secretion so wonderfully composed as that of *Dolium* has nothing in common with the saliva of the higher animals. Another eminent physiological chemist, Dr. R. Maly,† has lately studied this "saliva" and expresses similar doubts. He finds that, added to alkaline neutral or acid solutions, together with albumen fibrin or starch, it digests none of these substances. Neither could he detect any ferment in the

* 'Nature,' xxvi. (1882) pp. 559–64.

† SB. K.K. Akad. Wiss. (Wien), lxxxi. (1880) p. 376, and Monatsb. f. Chem., i. pp. 205–15.

" glands" themselves. He concludes that this acid fluid is of no use to the animal when once secreted, and he again directs attention to the peculiar structure of the so-called glandular organs, which much need a thorough re-examination.

Olfactory Organ of Parmacella.*—H. Simroth, dealing with the olfactory organ of this terrestrial pulmonate gasteropod, and with the question whether there is any relation between the olfactory sense and respiration, points out that the pulmonary tissue is extremely well developed, and that from the anterior edge of the respiratory space there extends into the mantle-cavity a shallow groove, bounded by two distinct ridges; these are in length at least equal to that of the transverse diameter of the body, they are richly provided with ganglion-cells, and traversed by bundles of muscular fibres. There can, then, be no doubt that we have here a sensory organ, and that that organ is olfactory in function.

Another question which arises is as to the homology of this part with the olfactory organ of aquatic gasteropods. The position and mode of innervation of the organ makes this very doubtful, and, taken in conjunction with the systematic position and life-history of the possessor, leads us to think that we have here to do with a recently acquired structure.

Innervation of the Mantle of Lamellibranchs.†—L. Vialleton has studied *Unio* and *Anodonta* by removing the mantle from its attachments in a living specimen, and placing it for 15 minutes in lemon juice, and then for about 20 in a 1 per cent. solution of chloride of gold. Feebly acidulated water is added, and, after 24–36 hours' maceration, the examination may be entered upon. In the portion of the mantle situated within the pallial impression, the nerves are found to be especially distributed along its two faces, a little below the epithelium; from their mode of union there result nodal points of varying form, and a plexus presenting spaces differing in shape and size; from each superficial plexus there are given off finer fibres, which either arise directly from larger nerves or from the finer branches of them; they finally divide into ultimate fibrils which form a closely-set subepithelial plexus. The whole arrangement may be compared to that which is found in the connective tissue of the cornea of the human eye. Observations on allied forms lead the author to believe that this arrangement is common to all Lamellibranchs.

Differentiation of Protoplasm in Nerve-fibres of Unionidæ.‡—In investigating this subject, J. Chatin, after treating with osmic acid, teases the nerve-fibres of *Unio pictorum*, *Anodonta cygnea*, &c., stains with carmine or anilin red, and mounts in glycerine. The axis of the fibre consists of a bundle of fibrils longitudinally arranged; around this bundle lies a protoplasmic layer containing nuclei here and there, but difficult to observe. The protoplasm is finely granular;

* Zool. Anzeig., v. (1882) pp. 473–5.
† Comptes Rendus, xciv. (1882) pp. 461–3.
‡ Ibid., pp. 1723–6.

it contains spheroidal refringent myeloid globules, coloured black by osmic acid; they multiply rapidly, but remain distinct and are comparable to the myelin of Vertebrata. Pigment-granules of a brownish or yellowish colour, found in some ganglia, are often seen in the protoplasm of the nerves; they are not altered by ether or chloroform. Transverse sections of the nerves show this protoplasmic layer to constitute the entire covering of the central fibrils, and to be approximately homogeneous in density throughout; although a slightly denser external zone is somewhat constant in its occurrence, it is not dense enough to be comparable to the Schwann's sheath of the Vertebrate nerve.

Molluscoida.

Disdaplia.*—A. Della Valle, in describing this new genus of the Synascidiæ, states that the tail of the larva presents the following constitution: there is an envelope of cellulose, with amœboid nuclei, a membrane continuous with the ectoderm, which is formed of large, flattened epithelial cells, a contractile layer of fusiform cells which are transversely striated, and the axis of the tail, which is more transparent than the rest, and is occupied by the hyaline cylinder, which is, according to some, a solid cartilaginous notochord; the author, however, like some other writers, finds that this axial structure is a hollow tube, the wall of which is continuous with that of the peritoneal sac.

Attention is to be directed to the fact that the first buds which are developed in a young colony have no sexual glands, but those that are derived from the later colonies (due themselves to the repeated fission of the primitive buds) present at once indications of these glands, or at least of groups of cells which will develope into them. The author promises to prove in a later work that this phenomenon is not peculiar to *Disdaplia*, but is to be seen in other Synascidians.

Natural History of Doliolum.†—B. Uljanin concludes that, in the developmental cycle of *Doliolum*, only two generations succeed one another; one of them is developed from the egg, is provided with a *stolo prolifer*, and gives rise to a generation of nurses; the other is derived asexually from the stolon, and this latter generation is polymorphous; the separate forms which constitute it have hitherto been regarded as special generations, and distinguished as lateral buds, median buds (second generation of nurses), and sexual forms; of these, the two former have rudiments of reproductive organs, which disappear during the course of development. *Doliolum* may be looked upon as a form which has inherited a process of alternation of generations from the *Synascidiæ* and *Pyrosomidæ*, and in which, owing to a slow diminution in the amount of nourishment, the nurse developed from the ovum has gradually been subjected to a series of adaptation, for the purpose of the preservation of the species. The want of true colonial life has diminished the amount of gemmation

* Arch. Ital. de Biol., i. (1882) pp. 193-203.
† Zool. Anzeig., v. (1882) pp. 429-36, 447-53.

and the thickness of the protecting mantle, which is here merely a feebly developed hyaline layer, derived from the ectoderm and without any special cells.

Development of Ganglion and Ciliated Sac in Pyrosoma.*— The ciliated sac, or " olfactory organ," has been studied by L. Joliet in the bud of this Tunicate. The walls of its canal consist of a cubical non-ciliated epithelium, a few cilia and flagella occurring, however, at the point at which it opens into the branchial sac ; the median tubercle is composed of a mass of small round cells, grouped round a diverticulum of the canal. The organ evidently represents the canal of the gland of the Ascidians proper, the anterior ciliated part corresponding to the " pavillon," and the median tubercle being apparently a rudimentary gland. Kowalewsky is wrong in speaking of a cavity within the ganglion, and of the obliteration of the cavity of the primitive neural canal, for he has mistaken the latter for the ganglion. The canal is constricted at each point at which a young bud is given off, and thus forms a pear-shaped vesicle within each older zooid, and its walls undergo modifications. From its hinder end, which thickens, some round cells between the vesicle and the ectoderm are detached ; these cells proliferate actively, and form an oval mass which grows round the posterior end of the vesicle, constituting the true ganglion in almost its adult form. The vesicle opens into a depression in the branchial sac, and becomes the ciliated sac of Huxley. Probably the neural canal of Ascidian larvæ also, of which the cerebral vesicle is a part, is only the rudiment of the canal of the subneural gland. The function of the canal in question is probably olfactory, a supposition favoured by its direct apposition against the ganglion; it is at any rate not excretory, as the ciliary currents set towards the bottom of the sac and not towards the exterior.

Development of Genital Products of Cheilostomatous Bryozoa.† —W. J. Vigelius has found a very suitable object for study in the arctic species *Flustra membranaceo-truncata*, where he finds that the ovary arises from the inner surface of the endocyst, and from that portion of the wall of the distal half of the zoœcium which lies opposite to the side which carries the operculum. Each ovary forms a small spherical or ellipsoidal body of a yellowish colour, which consists of a number of small, round, closely-packed cells. Although apparently isolated, it is connected with the endocyst, the small cells of which take part in its formation. A differentiation is soon seen in the primitively similar elements, for two (or, rarely, more) become distinguished by their size ; the other cells become set around these two ova, and the growth of the latter is accompanied by an increase in the size of the follicle, the cells of which apparently increase by division. When the ovarian cells have attained a certain size, there commences a struggle for existence. One grows more rapidly than the other, and the less fortunate one is driven to the periphery of the ovum, where it ceases to grow, although still quite distinctly an ovarian cell;

* Comptes Rendus, xciv. (1882) pp. 988-91.
† Biol. Centralbl., ii. (1882) pp. 435-42.

where there are more than two ova in one follicle, the same pheno-
menon obtains, one only continuing its further development.   About
this time the ovary lies free in the perigastric cavity.

Soon the yolk of the eggs becomes darker and granular, and
frequently so contracts that a peripheral space is left between it and
the egg-wall; as the nutrient material is used up, the central portion
of the follicle gradually becomes clearer and thinner, and by the
absorption of the cells a passage is left for the egg.   The free
egg is rounded or oval, and is generally of some size; its passage
into the brood-capsule is probably effected by muscular contractions.
The author comes to the conclusion that fertilization does not take
place in, but externally to the ovicells.   Hermaphrodite zoœcia were
rarely observed; but when they were, the arrangements were such as
to point to self-fertilization.   The eggs would seem to be developed
independently of the polypides.

The testes appear to be developed later than the ovaries, and not
at a definite point of the zoœcium; they are irregular in form, and
consist of masses or cords of rounded darkly-pigmented cells, very
similar in appearance to those of the primitive ovaries; the male
zoœcia are less numerous than the female.

The author thinks that there can be no doubt that the Bryozoa have
a general phylogenetic relation to the Rotifera, Mollusca, Chætopoda,
and Gephyrea (the Trochosphere-larva, Balfour); in their oogenesis
they have most marked resemblance to the Chætopoda and Gephyrea.

Arthropoda.

Brain of Crustacea and Insects.[*]—J. Bellonci, in an account of
the nervous system of *Sphæroma serratum*, whose brain appears to be
intermediate between that of Decapod Crustacea and that of Insects,
insists on what Berger and Claus have already shown, viz. that the
lateral enlargements of the brain of the higher Crustacea are not, as
Dietl supposed, the optic lobes, but that the optic ganglion is the true
optic centre and altogether corresponds to the optic lobes of insects.
In fact, in *Sphæroma*, as in *Nephrops*, the lateral swellings of the
median cerebral segments are the centres of origin for delicate fibrils
which belong to the antennary (interior) nerves, and they correspond,
both in relation and structure, to the antennary swellings of the brain
of insects.   So again, in Crustacea just as in Insects, the fibres from
the optic lobes penetrate between these swellings and the superior
lobes: and, if we consider that the swellings of the nerve of the
external antennæ are formations peculiar to the Crustacea, we see that
in them the lobes containing the olfactory "glomeruli" have just the
same relations to the œsophageal commissure as the same parts in
insects.   The parts which, in the Crustacea, are really homologous
with the fungiform bodies of insects are the internal lobes of the
superior cerebral segment.

The author supports his views by an account of the structure of the
brain of *Gryllotalpa;* at the same time he recognizes the marked

differences in the size and histological constitution of these regions which point to a much more elevated psychical function in insects. The great development of the swellings of the median cerebral segment in the higher Crustacea indicates that this region is very important from a psychical point of view. The further details of the structure of the brain and sensory organs of *Sphæroma* would require a number of figures for their satisfactory elucidation.

a. Insecta.

Want of Cutaneous Absorption in Aquatic Coleoptera.[*]—L. Frédéricq placed *Dytiscus marginalis* and other water-beetles in aqueous solutions of curare, or strychnine, a few drops of which were sufficient to poison a frog in a few minutes. The insects, however, lived in them for from 15 to 30 days, when the experiment was brought to an end. It is to be noted that Coleoptera may be poisoned by strychnine or curare, and the facts observed agree with the statement of F. Plateau that aquatic Coleoptera do not suffer from immersion in sea-water.

Habits of Ants, Bees, and Wasps.—Sir John Lubbock recently laid before the Linnean Society his tenth communication on this subject, containing an account of his further observations made during the past year.

The two queen ants which have lived with him since 1874, and which are now, therefore, no less than eight years old, are still alive and laid eggs last summer as usual. His oldest workers are seven years old.

Dr. Hermann Müller, in a recent review, had criticized his experiments on the colour sense of bees; but Sir John pointed out that he had anticipated the objections suggested, and had guarded against the supposed source of error. The difference was, moreover, not one of principle, nor does Dr. Müller question the main conclusions arrived at or doubt the preference of bees for blue, which, indeed, is strongly indicated by his own observations on flowers.

Sir John also recorded some further experiments with reference to the power of hearing. Some bees were trained to come to honey which was placed on a musical box on the lawn close to a window. The musical box was kept going for several hours a day for a fortnight. It was then brought into the house and placed out of sight, but at the open window, and only about seven yards from where it had been before. The bees, however, did not find the honey, though when it was once shown them they came to it readily enough. Other experiments with a microphone were without results. Every one knows that bees when swarming are popularly (and have been ever since the time of Aristotle) supposed to be influenced by clanging kettles, &c. Experienced apiarists are now disposed to doubt whether the noise has really any effect; but Sir John suggests that even if it has, with reference to which he expressed no opinion, it is possible

* Bull. R. Acad. Belg. Sci., iv. (1882) pp. 212–3.

that what the bees hear are not the loud, low sounds, but the higher overtones at the verge of or beyond our range of hearing.

As regards the industry of wasps, he timed a bee and a wasp, for each of which he provided a store of honey, and he found that the wasp began earlier in the morning, and worked on later in the day. He did not, however, quote this as proving greater industry on the part of the wasp, as it might be that they are less sensitive to cold. Moreover, though the bee's proboscis is admirably adapted to extract honey from tubular flowers, when the honey is exposed, as in this case, the wasp appears able to swallow it more rapidly. This particular wasp began work at four in the morning, and went on without any rest or intermission till a quarter to eight in the evening, during which time she paid 116 visits.

Larvæ and Pupæ of Diptera.*—In continuation of a former memoir,† Head-forester Beling describes the metamorphoses of 39 species of flies belonging to the families Tabanidæ, Leptidæ, Asilidæ, Empidæ, Dolichopidæ and Syrphidæ. He concludes by giving an analytical table, occupying four pages, in which the characters of the larvæ of 21 genera are contrasted in accordance with the dichotomic method.

Organs of Flight in Hemiptera.‡—L. Moleyre prefaces a statement of the result of his observations by pointing out that in most Hemiptera the part played by the anterior and posterior wings during flight is almost equally important. But the former (hemielytra) are usually horny, whilst the latter remain quite membranous. Each of the two pairs of wings having a distinct structure and capacity, it is indispensable that they should supplement one another and that perfect solidarity should exist between them in their different movements. The apparatus which serves to attach the wings to the hemielytra consequently acquires, from a physiological point of view, exceptional importance. Accordingly he has undertaken an examination of its conformation in the different groups of Hemiptera.

In the Cicadidæ the connecting apparatus is simplest. In them, as well as in *Fulgora* and some allied genera, the posterior margin of the hemielytron is folded underneath, starting from the middle, a deep furrow being formed, in which, at the moment of flight, a corresponding fold of the wing fits. In *Fulgora* the folded portion of the wing begins to be differentiated.

In the Membracidæ, the Cercopidæ, and the Iassidæ, the fold is reduced to a sort of plate inclined backwards on the plane of the wing, often bent into a semicircle and furnished at the extremity with fine serrations.

In the sub-order Heteroptera, it is the fold of the hemielytra, and not that of the wings, which is differentiated. There is also a connecting apparatus which is only found in certain families of Homoptera. In the groups where it attains its greatest development, it appears to

* Arch. f. Naturgesch., xlviii. (1882) pp. 187-240.
† Ibid., xli. (1875).
‡ Comptes Rendus, xcv. (1882) pp. 349-52.

be independent of the principal apparatus, and seems to act under special conditions.

In the Cercopidæ, whose wings present at the base of the anterior margin a triangular enlargement, the external side of the triangle is armed with a row of hooks, few, but very strong, whose extremities, sharply bent, are directed backwards. These hooks are also seen in the Tettigoniidæ and in *Ledra* where they are very small.

In some Membracidæ there are vestiges of these hooks in the shape of long straight hairs, inclined backwards. It is important to note that in *Ihelia expansa*, which has only two or three of these hairs, they occupy the widened region of the edge of the wing.

In *Cicada* and *Fulgora*, the principal connecting apparatus is continued as far as the base of the wing by a sort of marginal nervure, forming a very strongly marked rim.

Many of the Hemiptera fly but rarely; the flight of the Hymenoptera, more powerful and better directed, is therefore much more sustained, and from this comparison most naturalists seem to conclude that the organs of flight in the latter exhibit the highest degree of perfection. The author thinks, however, on the contrary, that the double function of the hemielytra, which serve at the same time both as wings and for sheaths, involves special complication in the form of the organs of flight.

β. Myriapoda.

Diversity of Type in Ancient Myriapods.[*]—S. H. Scudder discusses the systematic position of *Palæocampa* (Meek and Worthen), and comes to the conclusion that it is neither the caterpillar of a lepidopterous insect nor a worm, but a myriapod of a new and strange type.

This brings us face to face with two remarkable facts: First, that in this ancient myriapod, carrying us back as far as any traces of wingless tracheate arthropods have been found, and therefore presumably not far from the origin of this form of life upon the earth, we find dermal appendages of an extraordinarily high organization, more complicated than anything found in living arthropods, excepting the more varied scales of several orders of hexapods; a form of appendage which it would seem, on any genetic theory of development, must have required a vast time to produce, but which we now seem to find at the very threshold of the apparition of this type of arthropod life. Second, that at this early period, in marked contrast to what we find in other groups of articulated animals, the divergency of structure among myriapods was as great as it is to-day. The structural relations of myriapods and hexapods render it probable that the former preceded the latter; and in complete accordance with this expectation, the structural relations of the oldest fossil myriapods indicate their apparition at a period earlier than that to which the winged insects are hypothetically assigned. This would compel us to consider the earlier type as aquatic, for which we have presumptive evidence in

* Amer. Journ. Sci., xxiv. (1882) pp. 161-70.

the structure of the Euphoberidæ, and renders it all the more surprising that the penetrating researches of the last thirty-seven years, since the first Carboniferous myriapod was discovered, have not yielded the slightest trace of fossil myriapods below the coal-measures. This discrepancy between fact and hypothesis should, the author considers, stimulate to more searching investigations, particularly of those articulates of the older rocks whose affinities have not been satisfactorily settled.

<p style="text-align:center">γ. Arachnida.</p>

Observations on Scorpions.*—Professor Ray Lankester finds that in the scorpions there exists a similar pair of large coxal glands, having essentially the same structure and position as the coxal glands of *Limulus.* It does not seem possible to doubt that these are homologous structures. Though no external opening has been found as yet, in either the one case or the other, it is possible that such an opening exists. Though glands in a similar position (at the bases of the limbs or jaws) are found in other Arthropoda, there are none known which agree so closely in position and structure with either the coxal glands of *Limulus*, or of *Scorpio*, as these do with one another. Possibly such coxal glands are in all cases the modified and isolated representatives of the complete series of tubular glands (nephrida) found at the base of each leg in the archaic arthropod *Peripatus.*

The discovery of the existence of such corresponding organs goes a long way towards confirming the conclusion as to the close affinity of *Scorpio* and *Limulus* to which Professor Lankester had been led by the observation of numerous other structural coincidences.

Professor Lankester also adds a note † on the differences in the position of the ganglia of the ventral nerve-cord in three species of scorpion, in which he shows that an important anatomical difference obtains between the scorpions with triangular sternum (*Androctoni*) and those with pentagonal sternum (*Euscorpii, Buthi,* &c.). Whether the scorpions with bandlike sternum (*Telegoni*) differ from or agree with either of these types in respect of their nervous system, has yet to be discovered.

Insecticolous Acari.‡—A. Berlese first deals with *Hypopus*, and confirms the doctrine of Mégnin that these animals are heteromorphous nymphs of other *Sarcoptidæ*, and the same seems to be true of *Homopus, Trichodactylus,* and others; the pedunculated Uropoda are shown to be nymphs, and it is laid down that no Uropod can be judged to be adult until the presence of the genital operculum has been demonstrated. A number of adult *Acari* may attach themselves to insects, but, as a general rule, these migratory forms are not adult. Migration would appear to be determined by desiccation and starvation, and insects to be the principal agents in the rapid and extended diffusion of the *Acari.*

* Proc. Roy. Soc., xxxiv. (1882) pp. 95–101 (1 fig.).
† Ibid., pp. 101–4 (3 figs.).
‡ Arch. Ital. de Biol., i. (1882) pp. 279–81.

Sense-hairs of the Hydrachnida.[*]—Dr. G. Haller has obtained the material for his investigations from the Lake of Geneva, a locality which has already[†] added considerably to our knowledge of the systematic zoology of the group.

Olfactory hairs.—In *Atax* the long hairs of the first pair of legs occur chiefly on the lower and outer surfaces of the 2nd, 3rd, 4th, and 5th joints, and diminish in length towards the latter joint. They are sword-shaped. Almost all of them are inserted within certain excavated eminences of considerable size, which protect the base of the hair, while allowing of its free movement, and contain the ganglion from which proceeds the nervous twig which supplies the hair. The hair is traversed by a central cavity which opens to the exterior near the point by an extremely attenuated canal; a number of similar fine canals leave the central cavity, and open at the extremities of some fine teeth which fringe the posterior side of the hair. The function is probably olfactory, and thus the first pair of legs in *Atax* is equivalent physiologically to an antenna. Similar hairs occur in *Axona*, and on the two hind pairs of legs, as well as on the first, in *Atax* itself.

Scales and tactile hairs.—On the hinder and interior surfaces of the palps, where these hairs are absent, they are replaced by certain scales and tactile hairs. The former are very widely distributed among the *Acaridæ*, and in some *Oribatidæ* occur over the whole body as well as the extremities, or they may be confined to the body or to certain parts of it, or, as in *Atax*, to the extremities. In *Atax crassipes* they occur only in the first pair of legs, at considerable intervals, on the 2nd to the 5th joints; they have a lancet-like shape; the cavity branches and opens in the same way as that of the olfactory hairs, although in *Atax* the margin does not present the same thorn-like points for the canals to open into. Nerves have been observed in connection with the canals. The function of the scales is probably also olfactory.

Of the tactile hairs, already described by Haller elsewhere, two new forms are described. The hook-shaped form ends in a fine head, and is now stated to be connected with a nerve-fibre. The length and thickness remain constant in the same species, but vary enormously in different Acarids, the long and stout bristles of the ultimate and penultimate joints in the two anterior limbs of the *Dermaleichi* and *Atax*, and the short and weak hairs of the penultimate joint of the maxillary palps, being referable to the same type; a ring of very short hairs surrounds the margin of the body of *Uropoda clavus*.

The second form of tactile hair occurs only in a representative of a new genus, *Forelia*, from the Lake of Geneva; it occurs exclusively in the male, and is aggregated in large quantities, covering considerable areas; it may be either a short, slightly curved hair on a small chitinous eminence which is penetrated by a nerve-fibre, or such a hair may be accompanied by another of about half its length; locality, the end of the foot of *Atax*.

[*] Archiv f. Naturges., xlviii. (1882) pp. 32–46 (1 pl.).
[†] See Lebert's researches, this Journal, iii. (1880) p. 69.

The *antenniform* hair of Hydrachnida occurs at the anterior end of the body or, less frequently, on the back, in front of the insertion of the first pair of legs. It is very mobile, and is placed on a small eminence which is hollowed out so as to form a complete socket for its base; morphologically, it evidently represents the weak hairs which lie at the sides of the orifices of the cuticular glands of the back, as the duct of one of these glands opens close to it. The central canal does not send out fine tubes to the surface, as in the case of the olfactory hairs, but ends blindly; hence the function is probably simply tactile.

An *auditory* function is assigned, chiefly by a process of exclusive reasoning, to some very simple long bristles, pointed and pale in colour, which occur at long intervals on the legs. In *Eylaïs* a dagger-shaped hair with delicate fringing filaments clothes in great abundance the space between the epimeræ of the first four legs; it is supplied by a nerve on which a ganglion is placed within the ring which surrounds its base. Some stout, short hairs, placed on the upper edge of the labium in *Hydrodroma rubrum*, &c., resemble tactile organs, but are possibly, from their position, *gustatory*.

The spined elevation of the lower side of the second joint of the palp of *Limnesia* is, probably, simply intended to meet the opposed claw of the mandible, and is not specially sensory in its properties. The chitinous nail-like tips of the palps of the species of this order, must also be regarded only as grasping organs.

δ. Crustacea.

Ontogeny of Fresh-water Copepoda.*—J. A. Fric gives (in somewhat difficult French) a preliminary note on the ontogeny of fresh-water Copepods, principally confined to the genera *Cyclops*, *Diaptomus*, and *Canthocamptus*. Although it might be thought there was no room for further work in the apparently exhausted field of the anatomy and development of the Copepods, he found on the contrary a considerable number of facts hitherto unexplained.

The nervous system (brain, œsophageal collar, and ganglionic chain) and the alimentary canal are discussed in detail. In regard to nutrition and circulation the author refers to the fact that in this respect the Copepods formed an exception, hitherto unexplained, amongst the Crustacea. The nutritive liquid is set in motion, as is known, either by the heart, or by the regular alternations of the alimentary canal, in cases where the heart is not developed. But the blood-corpuscles, which are so numerous in the Phyllopods, have not, until now, been observed in any Copepod. Claus himself says, "It is remarkable that cellular elements (in the blood) are wanting, whilst they appear in such abundance in the allied Daphnidæ, and I have never been able to see blood-corpuscles even in the large, transparent, marine species."

It is now easy to understand why the lymphatic corpuscles have not been observed in the Copepods: they do not exist in the usual

* Zool. Anzeig., v. (1882) pp. 498-503.

form—forced in a mass with the nutritive liquid through the plexuses of the body—but they glide almost in the form of parasitic amœbæ over the muscles and the organs, nourished by the liquid of the body. In this form the author has observed them in *Cyclops* without a heart, as well as in the Calanidæ (*Diaptomus*) which have one; it is therefore very probable, or even certain, that they exist in the whole of the Copepoda. They are mesoblastic cells in movement during the whole of life, which participate, from their earliest stages, in the formation of the muscles and genital canals.

It is proposed to divide the genus *Cyclops* into two natural groups. The principal differences exist in the larval states of the nauplius and metanauplius, in which the characters are so different and so marked at first sight, that the possibility of a mistake is entirely excluded. The principal difference consists in the organization of the limbs.

In one of these groups—the Dolichopoda—which is evidently the oldest, all the limbs serve for locomotion, and only a few spines on the second and third pairs are for seizing nourishment. The second group—the Brachypoda—on the contrary is more perfectly organized; it is especially the third pair which is bent in the form of maxillæ and adapted exclusively for seizing nourishment. The spines also, at the base of the antennæ of the second pair, are adapted for this function. Whereas in the first group all the limbs extend far beyond the margin of the body, and the third is furnished with a long natatory branch, in the other group they are very short and robust, with the natatory appendage on the mandible very rudimentary.

Aberrant Oniscoids.[*]—The wood-lice are much neglected by English naturalists. They are well worthy the attention of microscopists who are not able to visit the seaside, and yet desire some path of inquiry affording more promise than the beaten anatomical tracks.

As a sample of what may be done in this direction we note a memoir by Dr. Max Weber on *Haplophthalmus* and *Trichoniscus*, genera enrolled in the exceptional sub-family of Trichoniscidæ. The structure of *Trichoniscus*, save in regard to externals, had not before been investigated. The copious details which such an essay contains must necessarily be studied in the original. Points of general interest, affecting other isopods, are duly indicated.

Dr. Weber makes a digression, more than eight pages long, on the subject of chromatophores. Leydig first showed that in the same situations as chromatophores are found cells without pigment, but otherwise similar, the whole forming one common system. Also animals of constant tint possess non-contractile cells, presumably homologous with chromatophores. Nerves are unquestionably distributed to the chromatophores. By means of gold chloride Dr. Weber has proved this connection in the case of a common isopod (a young *Philoscia*). Anger, fear, love and other emotions undoubtedly cause animals with chromatophores to change colour; yet it is usually assumed that the play of the chromatophores serves to hide their possessor, and perhaps in some cases for protection. But Leydig saw

* Arch. f. Mikr. Anat., xix. (1881) pp. 579-648 (2 pls.)

tree-frogs, amid their natural surroundings, change spontaneously their beautiful green for a dirty grey tint, just as they are known to do in captivity, especially during murky weather.   The inference follows, that a depressed temperature here acts on the chromatophores, particularly when we consider that these organs are an appanage of poecilothermous animals.   We learn from v. Platen, Moleschott, and Fubini, that light acting directly on the skin (apart from what is termed the chromatic function, or the indirect influence of light through the eyes) enhances the metamorphosis of tissue.   Dr. Weber concludes that one use at least of the chromatophores is to diminish the transparency of the skin, and thus lower the action of even moderate light when it begins to affect injuriously the organism.

Blind Subterranean Crustacea in New Zealand.*—The existence of blind Edriophthalmatous Crustacea in wells and subterranean cave-rivers in Europe has long been known, and now Mr. C. Chilton describes some new forms found in New Zealand.   They were obtained from a well at Eyreton, about six miles from Kaiapoi, North Canterbury ; the well had been excavated about seventeen years previously, was not more than twenty-five feet deep, and was fitted with a common suction-pump through the medium of which these new forms were obtained.   These proved to be three species of Amphipoda and one of Isopoda.   In none were there to be found in either the living or recent specimens the least trace of eyes.   The isopod is referred to a new genus *Cruregens*, and is most remarkable from the fact that it has only six pairs of appendages to the seven thoracic segments, whilst the normal number should be seven.   In many isopods the young have at first only six pairs of legs, the last thoracic segment being but slightly developed and destitute of appendages, and hence at first sight it might appear that the new form was but an immature state. Mr. Chilton, however, states that he has examined altogether twenty live specimens, none of which seemed otherwise to have anything immature about them, and these were obtained at various times from January to October 1881 ; he would, therefore, refer the absence of the seventh pair of appendages to an arrest of development.   In some respects the new genus resembles *Paranthura* of Spence Bate.   The new species is named *C. fontanus*.   The amphipods found with the isopod are *Cragonyx compactus* sp. nov., *Calliope subterranea* sp. nov., and *Gammarus fragilis* sp. nov., all without eyes.   The new species are all figured and at great length described.

Vermes.

Synthetic Annelid.†—A. Giard describes *Anoplonereis herrmanni*, a commensal of *Balanoglossus*, which appears to belong to the Lycorodidæ. But there are three tentacles, the proboscis is altogether unarmed, and there are no jaws or paragnathi.   The feet are all of the same characters, the notopodium being provided with a single process, and armed with simple capillary hairs.   Characters of this

* Trans. New Zealand Instit., xiv.   ' Nature,' 1882, pp. 542–3.
† Comptes Rendus, xcv. (1882) pp. 389–91.

kind distinguish this new form from any other Lycorid, while the appearance of the parapodia recalls what is seen in the Hesionidæ and certain Syllidæ ; in addition to this the presence of the third central antenna is a Syllidean character.   On the whole, therefore, *Anoplonereis* unites the Lycorididæ with the Hesionidæ and Polynoidæ on the one hand, and on the other with the Syllidea, which may be considered as being the ancestors of the whole group of Nereids, when that term is taken in a wide sense.

Elytra of Aphroditacean Annelids.[*]—Mr. W. A. Haswell has investigated the structure and functions of the elytra or scales, the possession of which is one of the most characteristic peculiarities of the Aphroditacea.

With regard to the functions of the elytra the author distinguishes (1) protection, (2) production of phosphorescent light, (3) sensation, (4) respiration, and (5) incubation.

The protective function is in some cases the predominating one. Thus in *Iphione* the scales are of extreme density, and cover the entire dorsal surface with a complete armour.   In others, the scales, though tough, are more readily detached, and in many instances do not completely cover the dorsal surface ; or are so delicate, and so readily parted with when the animal is irritated, that their direct protective action must be very slight.

When certain species of *Polynoë* are irritated in the dark a flash of phosphorescent light runs along the scales, each being illuminated with a vividness which makes it shine out like a shield of light, a dark spot near the centre representing the surface of attachment where the light-producing tissue would appear to be absent.   The irritation communicates itself from segment to segment, and if the stimulus be sufficiently powerful, flashes of phosphorescence may run along the whole series of elytra, one or more of which then become detached, the animal meanwhile moving away rapidly and leaving behind it the scale or scales still glowing with phosphorescent light.   The species in which the phenomenon of phosphorescence occurs are species characterized by the rapidity of their movements, and also by the readiness with which the scales are parted with ; and it seems not at all unlikely that the phosphorescence may have a protective action, the illuminated scales which are thrown off distracting the attention of the assailant in the dark recesses which the Polynoidæ usually frequent.

That the elytra act, like the dorsal cirri, as organs of some special sense, seems probable from their abundant innervation, as well as from the presence, in many instances, of fimbriæ and other appendages, some of which act as end-organs for the nerve-branches.

In *Aphrodita* and *Hermione* the scales have been observed by Williams and Quatrefages to perform an important mechanical function in connection with respiration.   In these genera the dorsal surface is covered with a coating of felted hairs, which stretch across

* Ann. and Mag. Nat. Hist., x. (1882) pp. 240-2. Proc. Linn. Soc. N. S. Wales, vii. (1882) pp. 250-99 (6 pls.).

from one side to the other, and enclose a canal open in front and behind, and having for its floor the dorsal wall of the body with the elytra and the "branchial" tubercles. These authors regard the oxygenation of the perivisceral fluid as taking place through the thin integument covering the scale-tubercles and the tubercles at the bases of the dorsal cirri, and have observed the scales to be subject to rhythmical movements, by means of which a current of water is driven continually over the dorsal surface, thus renewing the water in contact with the "branchiæ." In species in which the felt-like dorsal covering does not exist, this function would appear to be in abeyance; and in *Polynoë* and allied genera, so far as Mr. Haswell has observed, the elytra remain perfectly motionless while the animal as a whole is at rest.

The sexual products reach the exterior through apertures in the bases of the parapodia; and the ova are carried by ciliary action to the under surface of the scales, where they remain, adhering by means of a viscid matter, till the embryos are well advanced. Impregnation probably takes place while the eggs are in this situation.

Phosphorescent Organs of Tomopteris.[*]—In two new species of this genus of worms, described, from near the West Coast of Equatorial Africa, by Dr. R. Greef, under the names *T. Rolasi* and *T. Mariana*, the so-called "rosette-shaped organs" are represented not as eyes or glands as has been hitherto done, but as organs for producing light. In these species they are formed on the middle of the "rudder" of the parapodia as well as on the floats.

Under low magnifying powers they are seen to form sac-like spaces, enclosing a globose yellow oily mass which ultimately proves to be made up of a number of yellow tubes aggregated like the segments of an orange, thus producing the well-known rosette-like appearance. In *T. Mariana* the organs differ according to their position; those in the floats have the ordinary rosette-characters, but those of the rudders of the two front pairs of parapodia form two large organs occupying almost the entire breadth of the foot, lying near the inner wall of the ventral part; they are rosettes of a deep orange-yellow colour, enclosed in transparent rosette-shaped sacs. The tubes composing the rosette are filled with a granular substance. The organs are supplied with nerves on which ganglia occur over the sacs; from these ganglia proceed fine nerves which penetrate the sacs and reach the rosettes. Each of the segments, 6 to 11 in *T. Rolasi* and 8 to 11 in *Mariana*, exhibits a segmental organ near the point of projection of the parapodium from the body; it consists of a short curved ciliated canal with a large internal and somewhat smaller ventral external opening; the former has a frilled margin, the latter has sharp edges. On the ventral side of segments 4 and 5 in sexually mature females occur a pair of transverse genital slits.

Priapulus bicaudatus.[†]—R. Horst distinguishes in the cuticle of this Gephyrean two layers, the outer of which is thin and homo-

* Zool. Anzeig., v. (1882) pp. 384-7.
† Niederland. Arch. f. Zool., Suppl. Bd., i. (1882) Gephyrea, 13 pp.

gcneous, while the thicker inner one is made up of several super-imposed layers; the striking difference between the chemical reactions of the two is pointed out, and the differences in their appearance and structure detailed; to see them best the cuticle of the proboscis should be examined after maceration.

Dermal projections of various kinds are found on different parts of the body; the simplest are the papillæ which are found irregularly distributed on the rings of the trunk; they are blunt conical projections about $0\cdot1$ mm. long, are invested by a thin cuticle, and filled by a process of the hypodermis; the cells of the latter form a continuous layer, with the exception of the central portion where there is a mesh-work of nucleated fibres. The papillæ on the hinder edge of the last ring are not only distinguished by their greater length, but by the presence within them of a wide-meshed network of extremely fine fibres. Modified dermal papillæ are to be found on the costæ of the proboscis, where they form conical projections, the two lower thirds of which are invested in a kind of shield.

The description of the costæ of the proboscis given by Koren and Danielssen is stated to be incorrect, the glands described by them being merely integumentary canals cut across. Beneath the integument, and between it and the musculature there is at the anterior end of the body a space which communicates with the body-cavity by the intervals between the muscular bands.

Especial attention may be directed to the fact that for its whole length the nervous system is in connection with the ectoderm; it is essentially composed of extremely delicate fibrils covered by thicker fibres united into a plexus and passing into the cells of the hypodermis. Some corrections are made in the account given by the original describers of the female genital organs, and the male organs, which were not described by them, are stated to have the same form and position as the female, but instead of a lamellar they have a racemose structure, and the efferent duct is not superficial but principally internal. The nuclei of the cells were of considerable size, and the finely granular contents are divisible into a cortical and a medullary portion.

Anatomy of Ankylostoma duodenale.[*]—W. Schulthess gives a detailed description of this Nematoid, the length of which has been so very variously stated by different authors; the present investigator finds it to vary from 6 to 18 mm. After an account of the external form and the differences between the males and females, the writer passes to the integument, the two layers of which are described; in the study of the muscular layer we may distinguish the longitudinal lines, the muscles, and the papillæ; in dealing with the last, attention is directed to two hitherto undescribed structures; on the ventral surface of the male the skin, at one point on either side, is traversed by a fine subcuticular tissue, while in the female two similar structures are to be found near the tip of the tail; the significance of these bodies is only incompletely understood. The digestive tract is divisible

into the oral capsule, a highly complicated organ of fixation, an œsophagus and intestine; anal glands can only be definitely said to be present in the male. The author concludes with a history of the genital tract, which, well developed in either sex, is remarkably so in the female, where it would appear to be the cause of the greater size of the body. In a transverse section the genital tube may be cut through at least as many as ten times.

Structure of Trematodes.*—On the lungs of two tigers from the zoological gardens of Amsterdam and Hamburg, Dr. C. Kerbert discovered what he describes as a new species of *Distomum*, *D. westermani*. Two individuals were always found enclosed together in one horny capsule. All the organs of this fluke he has noted with care, and he discusses fully their histological characters. Save that he was not able to trace in his specimens the ciliated funnels at the ends of the finest branches of the excretory canals, as observed by Fraipont in *D. squamatum* and several ectoparasitic trematodes, he gives in the present memoir a complete account of almost every topic concerning the anatomy of trematodes in general.

Dr. Kerbert resolves the entire body of his *Distomum* into two strata, cortical and central. The latter is traversed by the dorso-ventral muscles and includes the various internal organs,—nervous, alimentary, excretory, and sexual.

The cortical stratum includes—the cuticle proper, the epidermis, the basal membrane ("cuticle" of authors), the tegumentary muscular layer, and the layer of tegumentary glands.

Two kinds of cells make up the splint-tissue constituting the bulk of the central stratum. The first are membraneless, of irregularly rounded figure, with finely granular contents and a conspicuous excentric nucleus or two nuclei. The other cells are branched; their branches unite to form a spongy network, in the meshes of which the round cells, usually isolated or in pairs, are included. In some places the meshes contain, instead of distinct cells, a protoplasmic residuum with imbedded nuclei. Here and there the trabeculæ appear under the guise of a very well developed fibrillar connective tissue, with fusiform nuclei among the several fibres. Just under the cortical stratum the cells of this connective tissue blend together into one granular mass of protoplasm, the so-called subcuticular layer.

As to the several organs, our space only permits us to notice briefly the sexual. These consist of (*a*) the genital sinus, (*b*) the male, and (*c*) the female organs. The genital pore, or common orifice of the whole apparatus, lies in the mid-ventral line, not very far behind the posterior sucker. The sinus itself is lined by a basal membrane, and is an invagination of the cortical stratum stripped of its epidermis. In general form the sinus is conical, with its apex turned backwards and inwards. The apex leads into the female conduit, or so-called uterus. The male opening is situate anteriorly, on the upper wall of the sinus, at its left side. The two, not quite

---

* Arch. f. Mikr. Anat., xix. (1881) pp. 529–78 (2 pls.).

symmetrical, irregularly lobed testes are placed dorsally in the hinder part of the animal. Their vasa deferentia unite in due course to form an ejaculatory duct, whose first portion acts the part of a seminal vesicle. Neither cirrus-pouch nor intromittent organ are present.

The female organs are—the ovary and oviduct, the vitellaria, the shell-gland, the canal of Laurer and the "uterus." The unpaired many-lobed *ovary*, somewhat dorsal in position, lies to the right of the ventral sucker. The conical continuous oviduct has its narrow end directed towards the shell-gland; where the oviduct ends the uterus begins. The paired *vitellaria* are made up of (*a*) the vitellarian glands, (*b*) their longitudinal collecting sinuses, (*c*) the two transverse ducts passing from these, (*d*) the rather long pear-shaped reservoir into which the transverse ducts debouch and (*e*) the yolk-duct proper into which it is continued. The *shell-gland*, a dense cluster of unicellular glandules, with interposed connective tissue, invests the innermost section of the uterus, where the yolk-duct and oviduct by their junction give rise to this conduit. Here also *Laurer's canal* arises; making two or three convolutions in its course it at length reaches the dorsal surface, where in the middle line its funnel-shaped opening appears, just in front of the transverse vitellarian ducts. A receptaculum seminis is appended to Laurer's canal not far from its junction with the uterus. The beginning of the *uterus*, hidden amidst the substance of the shell-gland and receiving the three ducts already mentioned, constitutes the "ootyp" of the elder Van Beneden, a term which Dr. Kerbert would extend to the adjoining part of the long winding tube which follows. The coiled vestibular portion of the uterus wholly occupies the space below the transverse vitellarian duct, on one side of the body, between the left diverticulum of the gut and the middle plane. Thus from the genital sinus we pass, by way of the uterus, to all the other female organs, and the whole gynæceum has two openings,—a ventral, leading into the sinus, and a dorsal belonging to Laurer's canal. The minute structure of the parts which make up this complex of glands and passages is described with very great clearness. The share taken by each in the formation or protection of the ova is also explained.

Against the possibility of self-fertilization among trematodes Dr. Kerbert urges many considerations. An internal vas deferens cannot be said to exist. The road by the uterus is not favourable to the transfer of spermatozoa. Most helminthologists, except Sommer, regard Laurer's canal as a vagina, which it is in the strictest sense,—an organ for copulation but not for parturition. The frequent occurrence of trematodes in pairs, the conformation of the body by which the back of one individual is closely applicable to the ventral surface of another, the position of the two external sexual orifices (equidistant in Dr. Kerbert's fluke from the anterior sucker), the presence of spermatozoa in Laurer's canal and their absence from the genital sinus or uterine coils—these are facts which at present favour the view, that the trematodes, if hermaphrodite morphologically, resemble snails and most monoclinous flowering plants in not being self-fertilizing.

Adaptation to Environment in the Trematoda.[*]—Prof. G. B. Ercolani finds that:—

1. The succession of phases of development is not always the same in all Trematoda; some leave the egg as a ciliated embryo, and require water; others, developed in terrestrial molluscs, have a non-ciliated embryo.

2. Nor are the different phases in development the same for all; the condition of encystation which is necessary for some is omitted in other species, which pass directly from the free *cercaria* into the free *Distomum*. There is, moreover, at least one exception to the rule that the larva must at one stage be agamic.

3. The well-known fact that certain nurses are reproduced by asexual generation (either gemmiparous or scissiparous, and the latter either endogenous or exogenous) was observed not only in simple sporocysts, but also in true *Rédiæ*. A special form of scissiparous generation was observed in the racemose sporocysts, where certain living parts are (as in Bryozoa and Hydrozoa) connected by atrophied stolons.

4. The direct conversion of the tail of a cercaria into a nurse was observed several times.

5. Encystation may not only be normal, but also accidental or abnormal; some die when, and at the place where, this accidental encystation takes place; others become, sometimes completely, but more frequently incompletely, adapted to this modification; in the latter case the generative organs are imperfectly developed, or are not developed at all. Examples of this are to be seen in the adaptation of *Cercaria echinula* to the intestine of the duck, dog, or rat; this species accommodates itself in different ways, so as to present different zoological characters, though these are not sufficiently distinguished one from another to justify the formation of distinct species. On the other hand, *Distomum mentulatum* may present quite definite specific differences.

The doctrine that each species of mollusc has a single determinate species of cercaria, corresponding to a single species of Trematode, is denied, and it is shown that, e. g. *Bytinia tentaculata* has as many as twelve different species of cercariæ. When exogenous gemmation obtains, the buds are produced at the hinder end of the body. While some forms have an excretory apparatus, composed of two vessels converging towards a buccal pore, others have no vessels or pores. As to the number of Distomata in one cyst, we had no definite information prior to the observation of Ercolani that from 20–80 larvæ might be found in large cysts on the peritoneum of tadpoles.

Vascular Organs of Trematoda.[†]—A. Villot points out that in the Trematoda, as in the Cestoda, there are a large number of canals which traverse the whole of the body, and open by a number of pores, either on the surface or into the intestine. Although they constitute but a single system, they may be divided into (1) a central

---

[*] Arch. Ital. Biol., i. (1882) pp. 439–53.
[†] Zool. Anzeig., v. (1882) pp. 505–8.

portion, represented by a contractile utriculus, which often extends throughout the whole length of the body, and ends at the caudal foramen ; (2) a median portion, consisting of branches of a medium size ; and (3) a peripheral portion, formed by a capillary plexus which penetrates all the organs and the parenchyma of the body.

In discussing the different morphological interpretations of these parts, the author expresses his opinion that the theory of Prof. Ray Lankester, according to which a portion represents the cœlom and the rest the nephridium, rests on an arbitrary distinction, inasmuch as there is nothing in the Platyhelminthes which corresponds to the internal orifices of the segmental organs of Annelids ; nor does the author find the explanations of Fraipont either satisfactory or new. Indeed, M. Villot is of opinion that later works have exhibited rather a step backwards ; the presence of a cœlom and of true segmental organs in these worms still remains to be demonstrated ; the vascular apparatus consisting of a single system of vessels, which are perfectly continuous and open only to the exterior or into the enteron.

Anatomy of Cestodes.*—Dr. Z. von Roboz has examined *Solenophorus megalocephalus.* In dealing with the cuticular structures, he finds that the cells forming the so-called subcuticular layer are connected both with one another and with the cuticle by a fairly well-developed, finely granulated, intercellular substance, in which fine fibrils of connective tissue are to be distinguished. The constituent cells differ in form in different parts, for, while they are elongated in the older joints, and have a finely granular protoplasm with a distinct nucleus and nucleolus, they are spindle-shaped in the scolex and the younger joints, and are connected by processes with the cuticle on the one hand and the interior of the body on the other ; the forms of these processes may vary considerably.

In regard to the water-vascular system, the most interesting discovery of the author would appear to be the demonstration of a special musculature for the longitudinal canals and their branches, an arrangement which seems to have escaped the observation of all previous investigators. The following will give some idea of what has been observed as to the nervous system :—Four nerve-cords are, altogether, given off from the ganglioniform enlargements which pass into one another at the region of the two suckers, and so give rise to the formation of a nerve-ring. Finer branches are thence given off, some of which pass into the suckers, while others give rise to the primary cords which pass into the proglottids ; the connection between the nerve-branches is such as to give rise to a nerve-plexus embracing the whole of the scolex.

It has been found that the oviduct is not merely formed by a thin homogeneous membrane, but that it is invested by an epithelium ; from the separate cells special hair-like structures, which call to mind cilia, project into the lumen of the tube ; but that they are really cilia was negatived by the length of time that the material for examination had been preserved. The vas deferens appears to be formed

* Zeitschr. f. wiss. Zool., xxxvii. (1882) pp. 263-85 (2 pls.).

of a thin structureless membrane, bounded internally by a single layer of cells; the penis has a very thick cuticle, and in *Solenophorus* is of some considerable length.

Studies on Cestodes.[*]—R. Moniez here treats chiefly of species of *Tænia*. In *T. pectinata* the uterus becomes modified very considerably in the older segments; its cæca become covered with a thick layer of granules which appear to result from luxuriant cellular proliferation of its walls. The granules become detached, and fall into the cavity of the uterus; some of them invest the embryos as a cuticular investment, and the rest form a reticulum which encloses the latter; a similar process takes place in *T. cucumerina*. The vessels in *T. pectinata* form numerous large anastomoses between each other. In another species, resembling *T. expansa*, *T. cucumerina*, &c., a possibly glandular mass is situated upon the oviduct, with cells each exhibiting an immense vacuole. The uterus forms two tubes extending from side to side of the segment, viz. on the ventral and dorsal surfaces, and lying on the muscular layer. When the uterus is full of ova, wide communications are seen between these main divisions. In *T. giardii*, the male organs are placed at the two ends of the segment; the spermatozoa of one side cross the segment and issue by the opposite vas deferens, the two currents crossing on the dorsal side. In young segments the vagina is very large, and the ovary appears by contrast to be merely an appendage of it, but later it envelopes and conceals it. The ovum does not exhibit the vitelline masses which appear towards the end of development in *T. expansa*. Besides the normal muscles are found some large fusiform cells, quite distinct from them, especially abundant in the central zone; in the old segments they are strongly refractive, and devoid of granules; they appear to be homologous with the mother-cells of the calcareous corpuscles. No vitellogenous glands exist in any of the species referred to.

Ligula and Schistocephalus.[†]—Herr F. Kiessling, working in the laboratory of Professor R. Leuckart, has detailed the structure of *Schistocephalus dimorphus* and *Ligula simplicissima*. He maintains the generic distinction of these tape-worms in opposition to Donnadieu, whose description of *Ligula* (published in Robin's Journal for 1877) he corrects in several particulars. As containing a revised account of two rather aberrant cestoids, presenting many noteworthy points of agreement, this essay has a value of its own; in so far as it deals with anatomical questions concerning tape-worms generally, it supports the views set forth by Herr Kiessling's teacher in the current edition of his great work.

These cestoids, when mature, inhabit the gut of water-birds. While *L. simplicissima*, in its asexual phase, infests malacopterous fishes, the larval *Schistocephalus* is a parasite of the body-cavity of the common stickleback. Both larvæ agree in being injurious to their hosts, so that external inspection reveals their presence. Curiously enough, *Schistocephalus* could not be found throughout a wide area

---

* Comptes Rendus, xciv. (1882) pp. 661–3.
† Arch. f. Naturgesch., xlviii. (1882) pp. 241–80 (2 pls.).

round Leipzig and Halle; near Berlin every second stickleback had its young tape-worm.

The complex sexual organs of *Schistocephalus* are here made intelligible by very clear figures. Why *Ligula*, as Leuckart has already shown, should differ, bird-wise, in having but one ovary, is not easily explained. In other respects the genitalia of the two worms are very similar. Herr Kiessling insists that there is not a fusion of two ovaries into one, as stated by Riehm to occur occasionally with *Tœnia rhopalocephala*.

New Floscularia.*—Dr. C. T. Hudson describes a new *Floscularia* (*F. regalis*), found by Mr. T. Bolton, on *Myriophyllum* in a pond near Birmingham, which also bore specimens of *F. campanulata*, *F. ambigua* (also one of Mr. Bolton's discoveries), *F. coronetta*, and *F. ornata*.

The new rotifer has a nearly circular cup-shaped disk, the edge of which bears six slightly recurved processes ending in knobs covered with long radiating setæ. The processes taper from their bases up to the knobs, and are set at regular distances round the cup, giving the rim quite a hexagonal appearance. The two processes which are nearest to the dorsal surface are shorter than the others, and between them rises a triangular lobe longer than any of the processes, and also crowned with a setæ-bearing knob. The disk is thus a kind of cross between that of *F. coronetta* and *F. ornata*, only with this hitherto unique distinction, viz. that there are *seven* processes issuing from it. All the previously known floscules have either five or three such processes; and there is only one known species that has the latter number, Mr. Hood's *F. trifolium*. Ehrenberg's six-lobed *F. proboscidea* is no doubt the five-lobed *F. campanulata*.

F. regalis is not one of the larger species. The majority of those hitherto seen were about $\frac{1}{60}$ of an inch, and the largest was $\frac{1}{56}$. The smaller, and probably younger, ones were unusually transparent for floscules. The two eyes were readily found on the dorsal side, both by direct and by dark ground illumination. Dr. Hudson was surprised, also, to find how easy it was to see the semicircle of small cilia which lies at the bottom of the cup on the ventral side. In the majority of the other species these are extremely difficult to make out. On the other hand, the tube of the new floscule was in every instance almost invisible. Its existence could just be made out, but that was all. No great stress ought, however, to be laid on this, as the tubes of all species vary very much according to their habitat. When fully expanded it usually extends outwards all the six linear processes, but curves inward the seventh triangular one over the cup-shaped disk, and uses both it and its setæ to prevent the escape of its prey.

Desiccation of Rotifers.—The Rev. Lord S. G. Osborne referring to a previous letter of Mr. Jabez Hogg as to the Rotifers and *Amœbæ*

* Midl. Natural., v. (1882) p. 252.

revived from " earth " taken from Durwaston, says * that it was
simply the dust of the garden which happened to deposit itself in
certain cup-like receptacles made artificially of a substance which
coated itself with an oxide, giving to the dust when wet a rusty
appearance. After having been in a drawer for more than three years
no symptom could be detected of a decrease in the number or activity
of the stock. He adds, " It is to me inexplicable that although I
have collected very many specimens of the rotifer (*R. vulgaris*) from
plants taken from ponds, I never could acclimatize these in my tanks,
so that they would bear the drying process so successfully as when
procured after my own fashion."

Echinodermata.

Heteractinism in Echinodermata.†—In dealing with a small col-
lection from Point de Galle, Professor F. Jeffrey Bell describes a
specimen of *Ophiomastix annulosa* in which one arm measures as much
as 300 mm. in length, and gives an account of another example, which,
as he calculates, may have had a total spread of 800 mm., or nearly
32 inches. He points out that such a form must be continually sub-
jected to the loss of part of an arm, but that owing to vegetative
repetition the loss will hardly perhaps affect the individual, and not at
all the species. Contrary to the opinion of such observers as Haeckel
and Simroth, he holds that such external irritation is not to be neglected
in discussing the question of heteractinism. There would appear to
be in all echinoderms a capacity for self-injury, which, in these days,
is excited by pain, fear, or anger ; while the starfish may only throw
off an arm, an ophiurid, in consequence of its greater centralization,
undergoes fission of the disk. The disk thus injured may give birth
to more arms than it has lost ; and when this habit becomes inherited,
we may get six-rayed forms ; such are to be found in *Ophiacantha*,
where, in some cases, there is so well-marked a cenogeny that, not
only are the adults sex-radiate, but the young are developed vivipar-
ously, and never exhibit any bilateral symmetry.

The origin of this tendency to self-mutilation is ancient and deep-
seated, for some polyactinic forms (*Brisinga*) lose their arms for the
purpose of setting free their genital products ; the tendency would
seem to be lost in those which, by the power of the spines, are able
to resist all foes, or those which by their capacity for vegetative
repetition are enabled to atone for it. When the tendency is seen in
others it has quite a different physiological significance, for the result
is true asexual reproduction.

Considerably modifying a table once given by Haeckel, Professor
Bell points out that in the Echinodermata we may have—

    A. Sexual reproduction.

        a. With metamorphosis (" metagenesis and internal gem-
           mation ").

        β. Without metamorphosis (viviparous Echinodermata).

* *Times,* 4th October, 1882.
† Ann. and Mag. Nat. Hist., x. (1882) pp. 218–25.

B. Asexual reproduction.
    a. Fission, with repair.
    β. External gemmation from a single arm.

In certain cases heteractinism would appear to be due to increased activity, consequent on inflammation.

Circulatory Apparatus of Regular Echinoids.*—R. Koehler describes the presence of two circular circumœsophageal vessels, and of two vessels in each ambulacral zone; he also proves the complete independence of the nervous and circulatory systems, and finds that this last communicates with the excretory organ by means of the sand-canal. The sand-canal is not simple, but is really formed of two, which are closely connected together; the only one which has as yet been described is independent of the ovoid gland of Perrier, or the organ of excretion, while the other is connected with it. Transverse sections of the sand-canal reveal the presence of one tube regularly lined by epithelium, and of another whose lumen is partly filled by bars of connective tissue which form a delicate reticulum supporting protoplasmic cells. The second canal, when it reaches the ovoid gland, increases in diameter, the partitions in its lumen become more numerous, while the gland itself consists, as in irregular Echinoids, of trabeculæ of connective tissue which are very delicate, and have their alveoli filled with protoplasm and pigmented bodies. The two circumœsophageal vessels communicate with one another at the level of the Polian vesicles.

Structure and Development of Ophiuroids.†— K. Nicolas Christo-Apostolides has at length published, in the French language, the full text of his memoir on Ophiuroids, with six plates. While availing himself of modern aids to histological research, he enjoyed the advantage of a copious supply of living specimens, and he rests his claims on the circumstance that he made good use of these as well as of preparations.

Five genera, including eight species, were examined. Not much is said of the skeleton and body-wall in the adult animal. The soft parts are minutely analyzed.‡ The simple sac-like alimentary canal, without mesenteries or free glandular appendages, consists of four separate layers—(*a*) an internal ciliated epithelium, (*b*) a brown layer with long (muscular) fibres, (*c*) a cellular (secretory) layer and (*d*) an investment of connective tissue. In this last are found peculiar triradiate calcareous spicules, the free ends of whose rays become again triradiate. There is a distinct, though short, œsophagus. The larval form has an anus, wanting in the adult.

Imprisoned brittle-stars, eight or ten days after being captured, show an opening in the middle of the back. Our author believes that, in consequence of starvation, a sinking of the dorsal wall takes place; this, with the central portion of the gut, becoming engaged among the five oral pieces, is bitten off as a substitute for food.

The existence of a circulatory system is denied, apart from the water-vessels and the general lacunæ of the body; albeit that these lacunæ are so disposed between the various internal organs, or these and the integument, as to present a certain definiteness in their arrangement. The true madreporic tube is figured with the pyriform gland (hitherto mistaken for a heart) placed beside it, the two being enclosed in a common investment strengthened with calcareous pieces and constituting the sand-canal of authors. The circular water-vessel of the larval brittle-star is closed from the first. Our author does not fully explain how it comes to surround the gullet. He simply says that the aquiferous system encroaches upon the digestive tube. Probably it slips over the rudimentary gut soon after the disappearance of the anus. The tubular ring, at an early period, sends forth five rays, each of which again gives off five cæca. Of these cæca the central one becomes the longitudinal ambulacral vessel of the arm; the adjoining cæca supply the first pair of tentacles; the two outer cæca represent the superior pair of buccal tentacles, whose common trunk elongates and produces the second pair. At first all five cæca have their points outwards; at a later stage the buccal pair turn in to face the mouth. The young Polian vesicle at first, also, grows from the circumference of the ring towards its centre; subsequently this direction is reversed. Not all brittle-stars have Polian vesicles. They are absent in *Ophiothrix versicolor*, which is thus distinguished from the common *O. rosula*, as likewise by its less convex arms and more variable tints.

While in certain Ophiuroids, e. g. *Ophioglypha*, the genital organs are appended to the respiratory pouches, as Ludwig has described them, they are in others more or less distinct. They are so far independent in *Ophiocoma nigra* that, when this species is dissected with its dorsal aspect upwards (in its natural position) the respiratory sacs must be removed before the genitalia can show themselves. In *Ophiothrix* each cluster of genital " glands " is replaced by a single organ.

The development of the Ophiuroids is described in the case of two species, *Ophiothrix versicolor* and *Amphiura squamata*. The first represents that section of the group in which there is an early oviposition and metamorphosis of the young; while *Amphiura*, further exceptional in being hermaphrodite, is viviparous. Nevertheless the organogeny of these two brittle-stars presents many more points of agreement than of difference. The resemblance of the free larva to the pluteus of the *Echini*, on which so much stress has been laid, is to be regarded as more superficial than real, and comparatively simple larval forms may occur beside those whose very striking transitory appendages render them rather abnormal than otherwise. The researches of Metschnikoff, the only observer since Müller who has contributed much to our knowledge of this subject, should be compared with those of our author. In many features the development of the Ophiuroids essentially approximates to that of the true starfishes, as first described with adequate fullness in the beautiful memoir for which we are indebted to the younger Agassiz.

On three important topics, demanding renewed inquiry, the

author differs from most embryologists. He supports (against Ludwig) the view, formerly urged by Lyman, that the oral skeleton is not made up of modified proximal elements of the arms, since it has an earlier and independent origin. The alimentary canal he describes as formed by delamination, not by invagination as in other echinoderms. Lastly, he contends that the two (rarely three) rudiments, from one of which the future water-system is derived, do not arise as diverticula of the digestive tube, but from cells which lie between it and the ectoderm of the embryo.

Formulæ for Comatulidæ.* — Professor F. Jeffrey Bell in an " Attempt to apply a method of formulation to the species of the Comatulidæ," deals with the two large genera *Antedon* and *Actinometra ;* these two forms he proposes to distinguish by the signs A and A' ; while for the brachials, distichals, and palmars he uses the letters B, D, and P, whenever their respective axillary forms a " syzygy " ; according as the first, second, or third brachial is a syzygy he adds the number 1, 2, or 3. Dealing with the cirri and their joints he divides both into three sets of few, moderate, or many ; these are distinguished by the letters *a, b.* and *c,* the cirrus-mark being placed above and the joint-mark below the fraction sign. A ten-rayed *Antedon* with 15 cirri of 40–50 joints, with the first syzygy on the third brachial, has its formula written $3 \text{ A} \frac{b}{c}$; a multiradiate *Actinometra* with its radial and palmar (though not its distichal) axillaries syzygies, with a syzygy on its first brachial, with less than 13 cirri and more than 40 cirrus-joints, has the formula $1 \text{ A}' \text{R} \text{ P} \frac{a}{c}.$ When a character is not constant it is placed in brackets, and when a multiradiate species has not any axillary in R, D, and P, its formula is placed under the mathematical sign of the square root.

Holothuroidea of the Norwegian North Sea Expedition.†—In another magnificent contribution to the fauna of the Arctic Seas, D. C. Danielssen and J. Koren describe in detail the new forms of which they have already published diagnoses. Of the seventeen genera in the collection five were new, and of the twenty-five species, six were new. *Kolga hyalina* is remarkable for the absence of fibrillar tissue from the subepithelial connective tissue, an arrangement known in no other Holothurian ; the calcareous ring is very imperfectly developed, and the sand-canal presents an embryonic condition in still remaining open ; the bilateral symmetry of this form does not, in the opinion of the authors, weigh sufficiently against the totality of their organization, to justify us in placing it high in the scale. In *Trochostoma thomsonii* well-defined vascular plexuses were seen in the wall of the rectum, but they do not seem, as in some insects, to have a respiratory function, but to serve as a system of lymphatic vessels. Two respiratory tubes are connected with the intestine, but there is no proper cloaca ; the madreporite is remarkable for its position, being

placed on the canal, but not at its extremity. *Ankyroderma* appears to be transitional between the Synaptidæ and the Molpadidæ.

Histology of Digestive Canal of Holothuria.*—E. Jourdan finds, in *Holothuria tubulosa*, that the cells of the epithelial or peritoneal layer are of two kinds; simple endothelial cells arranged in a single layer, cylindrical in form and often ciliated, while the others are of the type of mucous cells. The muscular layer is formed by circular and by longitudinal fibres, the former being continuous and regular, while the latter are most numerous in the anterior region of the tract, while, again, they are placed internally to the circular muscles anteriorly, and are external to them posteriorly. A number of lacunæ are to be found in the connective layer. The cells of the internal epithelial layer differ remarkably in different regions; while they are at first excessively long, and have the form of delicate fibrils, they are, further from the mouth, distinctly cylindrical. The glandular cells with granular contents are ovoid or spherical and appear to be confined to the more anterior regions, while the so-called mucous glandular cells are more widely distributed, with, however, considerable variations in their form, size, and number; in the more posterior portions of the intestine they may be compared to the mucous cells of the Vertebrata.

Cœlenterata.

Studies on Cœlenterates.†—Dr. O. Hamann finds that the cnido-cells are interstitial cells which have developed an urticating capsule in their interior and have then passed from the lower to the more superficial layer of the ectoderm; it may be shown by the presence of the nucleus after the formation of the capsule that this last owes its origin to the protoplasm of the cell. At the same time the cell is capable of producing a process which becomes connected with the supporting lamella, and has many if not all of its characters; this process is not a mode of communication from the exterior to the interior of the organism, but only a supporting fibre; if this view be the correct one it is clear that the cnido-cells cannot be looked upon as having a sensory function, but rather as being partly defensive and partly offensive.

In discussing the pseudopodioid cells of *Hydra* it is remarked that, if we examine the region of attachment we find that the ectodermal cells are here different from what they are in other parts of the body; cylindrical in form, their contents are not clear but finely granular; if separated, after maceration, they are seen to have only one and not two of the so-called muscular fibrils; and if carefully studied in the living specimen they may be seen to be capable of excreting mucus; if examined, when the animal is in movement they may be shown to protrude pseudopodia. No interstitial cells or cnido-cells are to be found in this region. The apparent absence of pseudopodioid cells in all other Cœlenterates leads the author to believe that *Hydra* is really a form standing very close to the ancestor of the Hydroid Polyps; though he recognizes the possibility of the objection being raised that *Hydra* has lost its skeleton in fresh water.

* Comptes Rendus, xcv. (1882) pp. 565–6.
† Jenaisch. Zeitschr. f. Naturwiss., xv. (1882) pp. 545–57 (2 pls.).

Organization of Hydroid Polyps.[*]—Dr. O. Hamann finds that in Hydroid Polyps there is rarely more than one—the longitudinal—axis; sometimes, however, the tentacles may be seen to be arranged along definite rays, so that the symmetrical arrangement of organs is not confined to the Medusæ; he shows that other genera besides *Tubularia* are provided with tæniolæ, and he uses the presence or absence of this character as an important aid to classification. In the Tæniolatæ he finds an endodermal musculature not only in the hypostome, to which it is confined in the Intæniolatæ, but also in the stomach.

True sensory cells or nerves were never detected in the ectoderm, and the structures which seemed to be such were found on closer examination to be merely interstitial cells. The endoderm of *Aglao-phenia* was found to be filled with yellow cells, which appeared to be unicellular algæ taken in for the purposes of nutrition. The cells of the ectoderm were found to be (1) epithelio-muscular cells, (2) proper epithelial cells, (3) interstitial, deeper-lying cells, (4) true muscle cells, (5) interstitial cells converted into cnido-cells, and (6) glandular cells; after describing these the author passes to the supporting lamella, which is nothing more than a structureless thin sheet, which is secreted from the endoderm.

In dealing with the origin of the Medusæ, Dr. Hamann starts from a polyp-stock, any cells of which might become an egg-cell or a sperm-cell; imagining that separate persons might become broken off or separated from the colony, we can suppose that if they become adapted to the new conditions they would continue to reproduce their kind, but they would at the same time be modified by their new life, become, in fact, *Medusæ*; it will be seen that the complete homology of the Polyp and Medusa is here recognized. The planula is stated to be always formed by delamination or by the wandering of ectodermal cells.

The relations of various Cœlenterata are exhibited in the following table :—

Siphonophora

Spongicolidæ

TÆNIOLATÆ | INTÆNIOLATÆ | HYDROCORALLINEÆ

Hydra | (1) Sertularinæ

(2) Campanularinæ

(Hydrusæ)
Archydra.
[*] Jenaisch. Zeitschr. f. Naturwiss., xv. (1882) pp. 473–544 (6 pls.).

In the classification of the Hydroid Polyps the absence or presence of the tæniolæ gives us I. *Intæniolatæ* with the families *Hydrina*, *Campanularinæ*, and *Sertularinæ*, and II. *Tæniolatæ*, divisible into the *Acolloblastæ* (with fourteen families), where the supporting lamella takes no part in the formation of the tæniolæ, and the *Colloblastæ* (with the families *Spongicolidæ* and *Scyphostomidæ*) where the supporting lamella enters into the tæniolæ.

A study of the histiogenesis of the Hydroid Polyps shows that any histological element, whether of the ectoderm or of the endoderm, is capable of becoming converted into a generative, muscular, glandular, or other cell; the part of the endoderm which lines the hypostome is regarded as having a secretory function, while that found in the gastric cavity is thought to be digestive. It is important to note that the author has convinced himself that ovarian or sperm-cells are sometimes derived from the ectoderm and sometimes from the endoderm, in face of the definite statements made by some authorities.

Hydra.[*]—C. F. Jickeli, having been attracted by the view of Brandt that *Hydra grisea* is but a young stage of *H. viridis* in which the symbiotic *Zoochlorella* has not yet appeared, has addressed himself to the study of the differences between these species. He finds characteristic marks in the form of the urticating capsules, sufficiently striking to enable one to distinguish, from a small piece of well-preserved ectoderm, from which form the piece was taken. Further than this, *H. grisea* has in its endodermal cells bodies of a yellowish colour, which take the place of the green bodies of *H. viridis*, and, as these do not seem to have been detected by Brandt, the author believes that that naturalist had under observation not *H. grisea* but *H. vulgaris* (*fusca*), and this view is confirmed by the fact that while *H. vulgaris* may, in some stations, be quite common in spring, it is very rare in summer when *H. viridis* is abundant.

Vital Phenomena of Actiniæ.[†]—B. Solger finds that the Actiniæ have no free enzymotic digestive secretion; treatment of the mesenterial filaments with water dissolves out a tryptic enzyma in *Sagartia* and *Anthea* and a peptic one in *Cerianthus*; the yellow bodies (or zooxanthellæ of Brandt) which are found in the cells of the endoderm are probably, the author thinks, foreign algæ. Neither the cells of the mesoderm nor of the ectoderm are capable of digesting albuminoid bodies; when a so-called anal pore is present (as in *Cerianthus*) it does not serve for the evacuation of the fæcal masses, but for that of the generative products and the expulsion of water. As to their respiratory phenomena, we find that Actiniæ reduce oxyhæmoglobin, but, on the other hand, there are great differences exhibited by them in their power of resisting oxygen-starvation, *Sagartia troglodytes* living for a long time, *S. parasitica* dying soon. Some concluding observations are made on the results of recent researches into the chemical constitution of these cœlenterates.

* Zool. Anzeig., v. (1882) pp. 491–3.
† Biol. Centralbl., ii. (1882) pp. 399–404.

Ovaries of Actiniæ.*—R. Hertwig finds in *Corallimorphus rigidus* that the smallest ova form groups of 2–4 cells between the bases of the epithelial cells, and that the larger reach almost to the surface of the epithelium ; an egg-cell taken in the act of passing outwards was seen to have part lying in the mesoderm and part in the endoderm ; the two halves were separated by a constriction which was sufficiently deep to affect the form of the nucleus. Young egg-cells are connected with the epithelium by a short cord ; when they leave this region their basal ends first pass into the mesoderm, and soon after the nucleus follows that portion. The filamentar apparatus of the egg-cell, which was only a temporary condition in this form, was more lasting in *Halcampa clavus*, a conical protoplasmic cord passing from the egg through the supporting lamella to the epithelium. Attention is directed to the peculiar form of the epithelial layer investing the egg, and to the curious fact that a similar phenomenon is to be observed in the Acraspedota, where the ova are likewise of endodermal origin.

Skeleton of Madrepores.†—The law of multiplication of the septa in hexaradiate corals, as first stated by Milne-Edwards and Haime, has gained a general if somewhat qualified acceptance. Schneider and Rötteken have proposed to modify it as regards the later and more puzzling stages of development. Semper seems to doubt the possibility of establishing the truth of any such formulæ, in the presence of the many and intricate variations which even the individuals of one species of coral may display. In his beautifully illustrated memoir on Astroides, Lacaze-Duthiers scarcely enters on the discussion of this question. We cannot cite any other zoologists who have made serious contributions to the subject.

G. v. Koch, however, who for years has studied the development and structure of the skeleton of the Anthozoa, now comes forward to introduce order where before there was chaos. Neither the law of Milne-Edwards nor that of Schneider are, in his opinion, supported by facts. Semper's scepticism has a certain justification, but must also be rejected. It may be accounted for as follows :—in one or more primary sectors the formation of new septa is liable to sustain a check ; thus septa of the second cycle belonging to such a sector may resemble those of the third cycle elsewhere in the same coral, and so with other cycles. Or, otherwise expressed, a hurried or retarded development of certain septa may here and there occur. Our author's hypothesis, wherein he sums up the general result of his own investigations, is certainly very simple and intelligible :—Throughout the Hexacorallia, both Imporosa and Perforata, an approximately contemporaneous formation of septa takes place within all the chambers of the calyx, so that the septa of each added cycle are equal in number to all the previous septa. Exceptions must be referred to direct modification or to inherited changes in the growth of the whole animal.

Herr Koch has proceeded by examining, in their proper order, successive slices of single specimens, carefully selected, cleaned, and filled with black sealing-wax. A number of corals belonging to the same species were thus analyzed, one by one, and afterwards compared with each other. *Caryophyllia cyathus* was chosen as representing the Imporosa, *Dendrophyllia ramea* the Perforata.

The simultaneous appearance of the first six septa contrasts with the very peculiar succession of the primary mesenteries. Herr Koch regards this succession as due to modification.

In the second section of his present essay Herr Koch maintains that the theca of each corallite among the Anthozoa is formed by secondary coalescence from its septa, and not independently within the body-wall. Four Mediterranean corals, including the two species noted above, appeared to show that the theca really arises in this manner.

Studies on Gorgoniadæ.[*]—G. v. Koch associates under the name of *Alcyonaria axifera* those eight-rayed corals which possess an internal axis but which do not have it, like *Corallium,* formed of fused spicules, but developed from an axial epithelium; such forms are *Gorgonia, Gorgonella, Muricea, Pruinoa,* &c. After describing some new or old species the author passes to an account of the development of *G. verrucosa;* the rounded or oval egg is surrounded by a hyaline envelope and has a stalk-like process of attachment; both these are invested by a cylindrical epithelium derived from the endoderm. The testes are distinguished from the ovaries by their generally paler coloration; the young spermatozoa are at first rounded, but later on get long delicate tails; fertilization is always effected within the mother-polyp, and, it is possible, before the egg breaks away from its stalk. In the later stages of segmentation the outer cell-layer becomes converted into a layer of cylindrical epithelium (ectoderm); the nuclei of these are smaller than those of the cells within, and the author has been able to confirm his earlier statement that the spicules are developed in the cells of the ectoderm.

[*] MT. Zool. Stat. Neapel, iii. (1882) pp. 537–51.

Development of Alcyonaria.[*]—A. Kowalevsky and A. F. Marion have studied the development of two species of *Clavularia* and of *Sympodium coralloides;* they find that, as regards the segmentation of the ovum, which has never yet been completely observed in an Alcyonarian, the fecundated ovum of *C. crassa* remains for some time without dividing, and the ordinary histological reagents fail to demonstrate the presence of any nucleus, though, after segmentation, the nuclei are, notwithstanding their small size, easily recognizable. There would appear to be so rapid a division that no two-sphere stage is to be made out, six segments being the smallest number that can first be recognized. A peripheral and a central mass are easily separable from one another, and the former soon gives rise to a well-marked ectodermic layer; the endoderm is not slow in its appearance, and the store of yolk becomes rapidly used up. The larva having become fixed, its narrower end is depressed, and gives rise by invagination to an œsophageal sac, the bottom of which becomes pierced and forms a means of communication between the mesenteric cavity and the exterior. Meanwhile the ectoderm has become thickened by the formation of a layer of connective tissue, which may be regarded as the pseudo-mesoderm. Cells migrating from without give rise, in *Sympodium*, to small calcareous nuclei which become the sclerites ; but in *Clavularia* the formation of the rudiments of these hard parts is delayed for some time.

Attention is also directed to the variations in the mode of development which are exhibited by *Sympodium*. While some larvæ undergo their changes rapidly, others retain their vermiform characters for a longer time, and in these there is no formation of sclerites, but the ectoderm is differentiated in the manner of *Clavularia ;* at the base of the pseudo-mesoderm there is formed a fibrous layer which corresponds to an annular muscular band. A large number of primitive mesenteric septa are developed, and the whole of the endoderm is supplied with a layer of longitudinal muscular fibres; a transverse section of these larvæ is almost exactly comparable to that of an Actinian.

Porifera.

Manual of the Sponges.—The first volume of Bronn's ' Thierreich,' on the Amorphozoa, written by Bronn himself, was published in 1859. It included the Protozoa and the Sponges. Bütschli having undertaken the second edition of the Protozoa, of which the thirteenth Lieferung has appeared, a revised account of the Sponges is no less imperatively called for. Upon Dr. Vosmaer[†] has devolved this task. The first Lieferung of his ' Porifera' is now before us; its contents are bibliographical and historical, with four plates. A good epitome of the researches of Oscar Schmidt, Eilhard Schulze, and others, is certainly much needed by students, no complete general work on the Sponges having hitherto been issued.

Development of Reniera filigrana.*—W. Marshall is led by his studies on this sponge to the conclusion that the Spongiæ represent a very old branch of the Cœlenterate stem, in which, in consequence of later adaptations and compressions, we have but a scanty phylogenetic history. Attention is directed to the view of Leuckart that the Porifera have a relation to the Cœlenterata in consequence of the homology of the ciliated cavity of the simple calcareous sponge (*Grantia*), with the body-cavity of a hydroid polyp, the mouth-orifices also correspond, and the pores of sponges are comparable to the water-spaces of the Cœlenterata. On the other hand, Balfour has insisted on the striking peculiarities of the sponge-larvæ, the early development of the mesoblast, and the remarkable characters of the digestive canals, as evidence in favour of the independent origin of the Poriferous phylum. To this Marshall answers that the larval peculiarities are chiefly to be seen in the Calcispongiæ, while the Fibrospongiæ have much more similarity to certain higher Cœlenterates (e. g. *Eucope*). The sessile condition of the sponges may be supposed to have conditioned the development of a skeleton, and this may be taken to be one of the causes of the marked development of the mesoderm. The entrance of the water-pores into the service of the digestive organs is looked upon as due to a change in function, which has again necessitated a greater development of the mesodermal tissues. It is next pointed out that in both groups we see a centrifugal canal system differentiated from the gastric cavity, which often breaks through the ectoderm and communicates with the exterior by permanent or inconstant pores; where there are tentacles present the canals or a part of them may be developed therein, and in some cases the pores opening from them to the exterior become so well developed that an astomatous condition is set up. In addition to this, the author believes that the ciliated investment of the tubes is derived from the endoderm layer. As to the absence of tentacles and stinging cells, attention is directed to the absence of both these organs from *Beroë*, and to the probability of their being nothing but the results of adaptation in the true Cœlenterata; while, further, their absence in sponges is to be explained by the present mode of nutrition exhibited by these forms.

Sponges and Cœlenterates are, then, Metazoa with gastric cavities and mesenterial pouches, with centrifugal canals arising from the former which may open to the exterior by pores and take in nutriment; they are invested by endodermal cells, which may become converted into flagellate cells. They are both developed from a common *Protactinian* stem-form.

New Fresh-water Sponges.—Mr. H. J. Carter describes † a new species of *Spongilla* from Bombay (*S. bombayensis*) of which only the statoblasts have been found. The most characteristic part of this species is, that the chitinous coat is spiculiferous, and that when the statoblast is divided through the middle or the outer layer crushed,

* Zeitschr. f. wiss. Zool., xxxvii. (1882) pp. 221–46 (2 pls.).
† Ann. and Mag. Nat. Hist., x. (1882) pp. 362–72 (1 pl.).

it also comes out divided or entire, as the case may be, when it may be mounted in Canada balsam. It then presents a damascened appearance, and becomes a very beautiful microscopical object, owing to the layer of spicules lying more or less parallel to each other, although in different directions, being immersed in the transparent light amber-coloured chitinous substance of which the coat is otherwise composed. The way in which the statoblast is firmly fixed to the stem of the herbaceous plant on which it was found, is also peculiar, inasmuch as the thick spiculiferous or external coat is continued on to the wood, thus forming a kind of neck or expanded base, which is so strongly attached as to bring away a portion of the wood when removed; while the " aperture," single or in plurality, varies in position on the *free* surface. They are for the most part more or less emptied of their germinal contents, and surrounded by a little sponge-structure, in which the skeleton spicules are found, one of which *being microspined*, at once distinguishes them from those of *S. alba* and *S. Carteri*, by whose statoblasts respectively and only they are frequently accompanied.

Mr. W. A. Haswell also describes * two new species of *Spongilla* (*S. sceptroides* and *S. botryoides*) from Brisbane, and *Meyenia Ramsayi* from New South Wales. Only one species of Australian fresh-water sponge has hitherto been described, being the one from Victoria, named by Bowerbank, *S. Capewelli*. Another species of *Meyenia* cannot yet be sufficiently determined from the few spicules found.

Protozoa.

Bütschli's Protozoa.—Nos. 10–13 of this part of Bronn's ' Thier-reich ' have appeared, with plates XVII.-XL. The classification of the Heliozoa is completed, and the *Radiolaria* also, which have nearly 150 pages devoted to them; it is pointed out, in dealing with the " parasites " of the Radiolaria, that their nutrition and metabolism are really essentially aided by the presence of those guests which are of vegetable origin. An account is given of the deformed creature which Haeckel called *Thalassicola sanguinolenta*, and which has been modified by the taking of foreign bodies into its extra-capsular sarcode. It would seem to be certain that some of the group are phosphorescent, but the author is not so confident that a number of the forms said to dwell at the bottom of deep oceans really do so, as nothing in the structure of many of them seems to afford any support to the doctrine. Following Hertwig the group is divided into the *Peripylea* and *Monopylea*, according to the characters of the central capsule; while the third division is that of the *Phæodaria* or *Tripylea*, of which little is as yet known.

The concluding pages begin an account of the Sporozoa, and there the Gregarinidæ are chiefly dealt with.

New Ciliate Infusorian.†—Mr. F. W. Phillips describes a new genus and species under the name of *Calyptotricha pleuronemoides*, found attached to *Myriophyllum*. The animals are furnished with a

* Proc. Linn. Soc. N. S. Wales, vii. (1882) pp. 208–10.
† Journ. Linn. Soc. (Zool.) xvi. (1882) pp. 476–8 (1 fig.).

remarkable transparent hyaline ovate lorica, opening teat-like at both ends, and a vibratory membranous hood or velum almost equal to the ventral length. The anterior extremity of the body is protrusible from the lorica. Their length is ·001 inch, and the non-vibratile setose body-cilia are about two-thirds of this length, with shorter stronger vibratile cilia at the entrance of the velum.

Actinophrys sol.[*]—Dr. A. Gruber, dealing with the fusion of two or more individuals in the Heliozoa, says, that unfortunately the signification of this process is still obscure, and we are not in a position to establish an analogy with the accurately investigated conjugation in the Infusoria, since no alteration in the nuclei of the united individuals has ever been observed, nor any fusion of the nuclei. The difficulties of observation are enhanced by the fact that it is often impossible to see the nucleus in the living animal.

As Dr. Gruber had recently a somewhat rich collection of *Actinophrys sol* at his disposal, he tried, with the aid of Korschelt's staining process,[†] to arrive at some conclusion upon these points. He has not, however, yet succeeded so well as might be desired, and must, he says, defer any decision until further observations have been made. He has, however, become acquainted with some other peculiar facts which are of interest, and which he thinks it advisable in the first place to make known.

Two specimens of *Actinophrys sol* were observed, one well-formed, and another only about a third or fourth of its size ; scarcely had the pseudopodia of the two touched than the smaller individual was quickly drawn to the larger, and united with it. After the union was complete, he fixed the animal and coloured it, when to his surprise only one nucleus was present. The experiment was repeated several times.

The first conclusion was that a union had taken place not only of the protoplasm, but also of the nuclei, but on fixing and colouring the objects *before* their union was completed, it was found that the small individuals did not contain any trace of a nucleus. Subsequent examination showed a large number of the small forms to be without any nucleus.

The rapidity with which the blending process takes place on the meeting of two individuals is remarkable : in from ten to fifteen minutes at the most, the small Heliozoa are absorbed by the large ones. It is the same when the *Actinophrys* does not take its fellow, but another organism, with this difference, however, that in that case the prey dies by contact with its enemy's pseudopodia, while the smaller individuals of the same species do not cease to show all the ordinary signs of life, indeed even an increased motion of the pseudopodia, and regular pulsation of the vacuoles. Once the author succeeded in bringing one after another three small ones to a larger one, and they were all fused in a very short time. During this process two flagellates were caught and devoured. Strangely

enough a fourth, and to all appearance similar small individual, was, as often as it was brought near to the larger, rejected, even though entangled in the pseudopodia in a manner which, in previous instances, had "produced an attraction like that of magnetism."

In all the above cases this blending of a nucleated individual with one or more small non-nucleated ones can have no other significance than that of a simple increase of the substance of the large *Actinophrys*, which in the last instance, after the absorption of three individuals, had reached its highest point, so that the animal resisted any further accretion.

On the question of conjugation, and the phenomena of reproduction connected with it, these observations throw no light; but the fact is demonstrated, that the Protista, which as perfect cells possess a nucleus, are yet able to live without. It may be objected that the small individuals may originate through some pathological process, and not through the normal fission of the larger *Actinophrys*. This can hardly be the sole explanation, for, first, Dr. Gruber has himself observed such fission in the *Actinophrys*, and it occurs still more frequently in the Infusoria, where one animal divides into several dissimilar fragments; while, secondly, he has found it to be the same with the non-nucleated as well as with the small nucleated examples.

All this, however, does not prevent our seeing in the non-nucleated *Actinophrys* their general vital phenomena similar to that of a perfect individual, for they show the most active protoplasmic movements in their changing pseudopodia, and possess an excretion vacuole which pulsates as in the normal animal, and they are also in a position to take nourishment, and to digest it in another vacuole.

A difference between the nucleated and non-nucleated animals may lie in the fact that in the act of blending, the *rôle* of the smaller creature is simply passive, so that the conscious action (if the expression may be allowed) is only on the part of the normal individual. But even this failed in the following observation: An individual equal in size to a full-grown *Actinophrys*, which, however, raised the suspicion that it had no nucleus, was placed close to a small one, whereupon the same process of union occurred as before. The larger one, however, had no trace of a nucleus any more than the smaller, although it had behaved as a nucleated animal. This case shows also that the non-nucleated *Actinophrys* is capable of growing.

The author, therefore, draws the following conclusions from his observations:—The nucleus has no relation whatever to the part which movement, nutrition, excretion, and growth play in the surrounding protoplasm, nor to any of the physiological processes of the cell-body not directly connected with reproduction.

In the Monera, which possess no nuclei, this is easily understood, but with the higher Protozoa, which normally always possess them, we could hardly have expected to find their influence so wanting. Neither can the shape of these creatures which, contrary to the formless masses of the Monera, is more or less regular or constant, be imputed to the influence of the nucleus, since the non-nucleated *Actinophrys* maintain the normal form.

Nuclei of Lieberkuehnia.*—This fresh-water rhizopod was first described by Claparède and Lachmann, and afterwards by Cienkowski, under the new name of *Gromia paludosa.* The observations of these authors are, however, E. Maupas considers, far from being complete ; and, moreover, are erroneous in some essential points.

The form of the body is variable, and may be perfectly spherical, ovoid, oblong, or even fusiform. Each individual can assume all these forms ; and when the same specimen is under observation during several days, it is seen to pass through all these changes. These changes take place very slowly. The carapace is very transparent, and is closely applied to the surface of the body, and changes with it. It also shares in the fissiparous division. It cannot, therefore, be regarded as a true carapace, like that of the *Arcellæ* and the *Difflugiæ,* where the carapace is a product of chitinous secretion of the nature of a skeleton, and has a very different morphological value. In *Lieberkuehnia* the seeming carapace is in reality only an integument or ectosarc, which can be isolated by certain reagents from the endosarc.

The pseudopodia are capable of extending to a length of $2 \cdot 26$ mm., the body of the animal having a diameter of from $0 \cdot 15$ to $0 \cdot 16$ mm. The circulatory movement of the sarcode is one of the most rapid yet observed. The granules move through a space of $0 \cdot 66$ mm. a minute. The Infusoria which strike the meshes of their network are rendered motionless, and in this way *Lieberkuehnia* is able to capture large Infusoria, such as *Paramecium aurelia.* Sometimes the Infusoria are swallowed whole ; sometimes the sarcode of the pseudopodia envelopes them on every side, and constitutes around them a digestive vacuole, in which they are dissolved outside of, and frequently at some distance from, the body. They do not reach this till later on, when they are already assimilated to the substance of the pseudopodia in whose circulatory movement they disappear. The digestion takes place, and is finished, entirely outside of the body. With small Infusoria, such as *Cyclidium glaucoma,* the operation hardly lasts five or six minutes ; but *Paramecium aurelia* resists more than an hour. The sarcode of the mass of the body is in constant motion, not regularly in the same direction, like the cyclosis in *Paramecium aurelia,* but split up into currents with varying directions. This sarcode is hollowed out by numerous vacuoles of different volume and size, which are carried along by the currents, in which they are often seen to change their form, and sometimes to amalgamate one with another. They always end by coming to the periphery of the body, where they contract in a similar manner to that of the so-called contractile vacuoles. *Lieberkuehnia* is therefore not, as has been stated, destitute of these organs of excretion. It is, on the contrary, perhaps more richly furnished with them than many other Protozoa. There is simply this difference, that the contractile vacuoles are neither permanent nor localized in any region of the body, every part of which may serve as a basis for their formation.

* Comptes Rendus, xcv. (1882) pp. 191–4. Ann. and Mag. Nat. Hist., x. (1882) pp. 410–13.

Contrary also to what has been asserted, *Lieberkuehnia* likewise possesses a great number of *nuclei*, spherical, and measuring 4 μ. It also increases by transverse division, as described by Cienkowski, but M. Maupas has seen individuals divide not only into two but into three. The body lengthened out into a long spindle, which, after the formation of two new peduncles bearing pseudopodia, became constricted at two points, and was thus divided into three nearly equal segments. One specimen, resulting from one of these divisions into three, developed, as soon as it was detached, a second peduncle bearing pseudopodia, situated at the opposite extremity to the one it already possessed. It continued thus to live with two places of emission of largely expanded pseudopodia. It was observed in this state for more than a day without any further changes taking place than those slow ones in the form of the body above-mentioned. In this, therefore, there was no preparation for a further fissiparous division, and the *Lieberkuehnia*, so constituted, with its two places of emission of pseudopodia situated at the two opposite extremities, would answer to the morphological type which has served to establish the family of the Amphistomina. It may be considered, therefore, one of those intermediate forms which connect separated families.

Parasitic Protozoa.[*]—J. Kunstler describes five new parasitic Protozoa found by him.

The first is a flagellate living in the intestine of the larva of *Melolontha vulgaris*, having a body which is elongated, flattened, rounded anteriorly and pointed posteriorly, and seems covered with longitudinal ribs more or less anastomosed; it is often depressed at the sides, so as to have two lateral wings. At its anterior extremity are inserted six long striated flagella which give it a jerking movement. In well-developed individuals other filaments (sometimes fifteen in number) are frequently seen in the shape of a narrow spearhead, very much elongated and a little distorted, which are attached to the most diverse parts of the body, and are agitated with a continual quivering movement. Near to the point of insertion of the flagella there is a buccal aperture which is connected, by means of a short and narrow canal, with a clear oval space occupying the central region of the body, which seems to be a digestive cavity. On the right of this region there is often found a sort of vesicle whose appearance recalls that of a contractile vesicle.

Another flagellate is frequently found with the preceding one, somewhat similar to it; but its body, which is not ribbed, is more globular and shorter, and it has only four flagella.

The larva of *Oryctes nasicornis* is also the habitation of an organism smaller and more delicate than the preceding; it dies and disappears very quickly in preparations. Only two flagella were seen.

The intestine of the tadpole is often inhabited by a flagellate, which differs considerably from *Trichomonas batrachorum* Perty. It has six superior flagella, and a lower trailing filament; it has a rather

long tail, of striated muscular structure, larger than the flagella, and sometimes even double; its form is somewhat variable, and it is destitute of the ridge and serrated crest which is seen in *Trichomonas.*

In this same intestine was found a remarkable organism, *Giardia agilis,* which the author thinks ought to occupy an intermediate place between "certain Schizomycetes, such as *Vibrio, Spirillum,* and the Monads." The body is formed of two clearly distinct portions: the upper and larger one has large vacuoles; the lower is much narrower, thicker, almost filiform, and resembling the large body of a *Vibrio;* but its length is much greater, and it terminates in a fine point. Between these two regions there is a slight constriction. From the lower circumference of the former portion long flagella proceed in a downward direction, which often remain attached to the narrow portion for varying distances; two other flagella are inserted at the inferior free extremity. The narrow portion is very mobile and very flexible; it constitutes a locomotive organ of very great power, and consequently the organism moves with remarkable activity. This kind of tail has an undulatory movement, similar to that of the tail of a tadpole, but at the same time it has a movement of "circumduction," and the combination of these two movements gives to it a helicoidal motion of remarkable vivacity.

Intestinal Parasites of Oysters.*—A. Certes has found, in the oyster, *Hexamita inflata,* which is also found in the brackish waters of the region he studied; in addition to forms which presented two posterior filaments there were some observed that had four, and these are regarded as individuals undergoing longitudinal fission. The most interesting parasite was a new species of *Trypanosoma — T. balbianii,* which has at first sight the appearance of a large *Spirillum.* The action of the vapour of osmic acid, or iodized serum, and methyl-blue reveals the presence of a membrane, which is not rigid, but which appears to be contractile, and to obey the will of the animal; no mouth, anus, or contractile vacuole were to be detected in the interior, nor is there any nucleus or nucleolus; so that it is a Moneron with an undulating membrane.

BOTANY.

A. GENERAL, including Embryology and Histology of the Phanerogamia.

Structure and Movement of Protoplasm.†—G. Klebs gives a useful summary of the present state of our knowledge respecting the structure of protoplasm and the movements to which it is subject, and the connection between these two. He sums up by saying that, while we are still ignorant of the chemical composition of protoplasm, and of the mechanical forces which lie at the base of its mobility, it becomes

---

* Comptes Rendus, xcv. (1882) pp. 463–5.
† Biol. Centralbl., i. (1881) pp. 577–94.

more and more evident that the life of all living organisms depends on the vitality of this one and the same substance.

Protoplasm of Compound Laticiferous Tubes.*—The presence of protoplasm in laticiferous vessels was not detected by the older botanists; it has, however, been recognized in the compound laticiferous tubes of the Euphorbiaceæ, Urticaceæ, Apocynaceæ, and Asclepiadeæ. E. Schmidt now adds to this list the following orders:— In the Cichoriaceæ, protoplasmic sac and nuclei were detected in *Scorzonera hispanica* and species of *Sonchus;* in Campanulaceæ, in *Campanula ramosissima;* in Lobeliaceæ, in *Siphocampylos bicolor;* and in Papaveraceæ, in *Papaver*. In *Chelidonium* the coalescence of the individual cells is imperfect; and the protoplasmic sac and nucleus could be made out in each separate cell. The same is the case with *Carica Papaya* among Papayaceæ. In *Caladium marmoratum,* among Aroideæ, similar results were obtained. The so-called laticiferous tubes of Musaceæ are regarded by the author as rows of superposed tubes the contents of which are only locally in communication with one another; no nucleus or living protoplasmic sac could be detected in them. In many cases, and especially in the Musaceæ, it is very easy to mistake the coagulated latex for true protoplasm.

In all the plants observed which contained compound laticiferous tubes, the protoplasm of the individual cells coalesces into a large " symplast," which retains its optical and colouring properties to the last without change. The nuclei also remain in the vessels after the fusion of the cells without any alteration of form or structure till the complete maturity of the organ. It is not probable that any division of the nuclei takes place after the fusion. The vitality of the protoplasmic sac appears to be established by the following facts. In many cases the fusion takes place before the organ has attained its full size. If the mature vessels are injured, the protoplasm has also the power of repairing the wound, as in the multinucleated Siphoneæ, and in many pollen-tubes. This is effected by annular thickening ridges on the wall of the tube, which finally completely close up the wound, the substance of these thickenings being identical with that of the callus of sieve-tubes. An additional proof of the vitality of the protoplasm is that, after the growth of the wall of the vessel is completed, it increases in thickness over its whole surface; and further, in the living plant, the latex cannot be coagulated by contact with water of imbibition. The latex, which is formed subsequently to the fusion, can also be regarded only as the product of a living protoplasm in the laticiferous vessels.

Development of the Embryo-sac.†—As a sequel to his researches on the embryo-sac of Leguminosæ,‡ L. Guignard gives an historical *résumé* of our knowledge of the structure of this organ in various natural families of plants, derived from his own observations and those of others. The following is an epitome of the general results :— The embryo-sac never arises from the fusion of two cells, but

* Bot. Ztg., xl. (1882) pp. 435–48, 451–66 (1 pl.).
† Ann. Sci. Nat. (Bot.) xiii. (1882) pp. 136–99 (5 pls.).
‡ See this Journal, *ante*, p. 644.

always from the increase in size of one only. While this cell is usually the lower daughter-cell among those which arise from the mother-cell, it may be any one of the others, thus establishing a certain equivalence among them. In the latter case only are there one or more anticlinals. Sometimes the axile hypodermal cell of the nucellus divides, giving rise immediately, in contact with the epidermis, to an apical cell, or initial cell of the calotte, and below to a subapical cell or mother-cell of the embryo-sac; sometimes it is itself the mother-cell of the embryo-sac. Both these forms occur among monocotyledons and apopetalous dicotyledons, but among gamopetalous dicotyledons the former only has been met with.

Among monocotyledons the mother-cell either remains undivided, or divides into a variable number of daughter-cells; in the former case it developes directly into the embryo-sac. Among apopetalous dicotyledons several mother-cells may develope, and in some cases this phenomenon seems to be constant; but ultimately there is never more than one embryo-sac. The mother-cell gives birth either to three daughter-cells in basipetal order, or to four secondary ones formed by bipartition of the primary daughter-cells, or even to a large number. Among gamopetalous dicotyledons the formation of four secondary daughter-cells seems to be normal.

In the greater part of angiosperms the mother-cell of the embryo-sac is the lower daughter-cell; but there are exceptions to this rule. The tendency of the other daughter-cells to develope into the embryo-sac is manifested by the frequent development of two adjacent cells, the nuclei of which divide like that of the mother-cell of the embryo-sac. The walls of the daughter-cells are often thick, refringent, and present some analogy to those of the anther.

The number of cells of the female apparatus and of antipodal cells is remarkably constant, apart from well-known exceptions, as *Santalum*, *Gomphrena*, and *Loranthus*; but their form and disposition are very variable. Among monocotyledons the synergidæ occupy the summit of the embryo-sac; they are usually ovoid, and provided with a vacuole. The oosphere is inserted either at the same level at the summit, or lower down laterally. The antipodals often remain very small, or sometimes become almost as large as the sexual cells; occasionally they even divide. The fusion of the polar nuclei often takes place towards the centre of the embryo-sac, rarely in its upper part. Among apopetalæ the synergidæ are situated at the summit, and are rarely without a vacuole when mature. The oosphere is distinguished by its nucleus, situated at the base; it is inserted laterally, and generally descends much lower than the two synergidæ. The antipodals are sometimes small, sometimes large. The fusion of the polar nuclei takes place towards the centre or towards the apex. Among gamopetalæ the synergidæ, placed on each side of the plane of symmetry, have a characteristic form; in the majority of cases they are elongated, and contract to a point at the summit; they have a large vacuole. The oosphere is always inserted laterally, and its nucleus is larger than that of the synergidæ. The antipodals are rarely

placed at the same level; more often they are superposed; sometimes they multiply, and form a tissue of a special nature. The fusion of the polar nuclei takes place towards the centre of the sac, or higher up, near the oosphere.

The author then traces the genetic history of the embryo-sac of angiosperms through the various classes of the higher cryptogams, and finally through the gymnosperms. The pollen-grain of gymnosperms, in which Strasburger has demonstrated the existence of a single partition, presents a close analogy to the microspore of *Selaginella*. One of the two cells developes into the pollen-tube, and represents an antheridium; the other is equivalent to a rudimentary male prothallium. The naked cells, observed by Hofmeister and Strasburger at the extremity of the pollen-tube, may be compared to the mother-cells of antherozoids, and complete the analogy, which is rendered more evident by comparing the mode of formation of the microspores of vascular cryptogams with that of the pollen-grains of gymnosperms. The researches of Strasburger and Elfving have shown the existence of a similar division-wall in the pollen-grain of angiosperms. Two cells are thus formed; one of these, the vegetative cell, further divides into a prothallium of two or three cells; the other, the nucleus of which has not been observed to divide, except in the Cycadeæ, becomes the pollen-tube; the nucleus, situated at the extremity of the tube, appears to play an important part in the process of fecundation.

As regards the homology of the female organs, the author contends that the facts support Strasburger's theory that the embryo-sac is the homologue of the macrospore of the higher cryptogams, and not the nucellus, as Warming maintains, a view which is inconsistent with the remarkable phenomenon of the fusion of the polar nuclei. The female prothallium is represented in gymnosperms by the endosperm, in angiosperms by the antipodals and the two polar nuclei; the synergidæ are endosperm-cells endowed with a special function; and the endosperm of angiosperms, which is formed only after fecundation, by division of the secondary nucleus of the embryo-sac, is the result of the resumption of an interrupted development.

Development of the Embryo in Lupinus.[*]—An apparent anomaly in the embryogeny of certain species of *Lupinus* is explained by L. Guignard as due to differences in the structure of the ovule. The species of the genus may be divided into two groups, according to the number of ovular integuments; one group, represented by *L. polyphyllus*, having only one integument; the other, represented by *L. luteus*, having two; and this is correlated with a difference in the structure and development of the suspensor or proembryo. The number of pairs of cells of which the suspensor is composed, and consequently the length of this organ, varies with the species; but in all those which have only one integument, it finally becomes disintegrated, and the cells which constituted it arrange themselves on the median line from the micropyle to the embryo, which is always

[*] Bull. Soc. Bot. France, xviii. (1881) pp. 231–5. See this Journal, *ante*, p. 644.

situated at the base of the cavity, at about equal distances from the chalaza and the micropyle. These disintegrated proembryonic cells were taken by Hegelmaier for a special organ, peculiar to *Lupinus*, formed before fertilization. In the species with two integuments this phenomenon is not presented, owing to the permanent coherence of the cells of which the suspensor is composed.

Homology of the Ovule.[*]—F. Pax describes in detail instances of phyllody of the carpels in *Aquilegia vulgaris* and *formosa*, with especial reference to the genetic morphology of the ovule. He comes to the same conclusion as Brongniart and Celakovsky,[†] that the two integuments of the ovule together constitute a leaflet, on the upper side of which the nucellus is equivalent to a metablast. The identity of this leaflet with a pinnule of a fertile fern-frond is evident; and the homologies of the parts may be expressed as follows:—

Fern.	*Ovule.*
Spore.	
Macrospore.	Embryo-sac.
Macrosporangium.	Nucellus.
Sorus.	Several nucelli.
Pinnule.	Ovular leaflet.

Reproductive Organs of Cycadeæ.[‡] — An examination of the reproductive organs of several species of Cycadeæ leads M. Treub to the following general conclusions:—

Each scale of the female cone (in *Ceratozamia longifolia*) bears two sporangiferous lobes, each of which gives birth to a macrosporangium. The macrosporangium can be detected in the interior of the lobe before any external differentiation is perceptible. In each macrosporangium can be recognized, at a later period, the three following parts:— (1) the reproductive or primordial cells; (2) in the interior an external parietal layer; and (3) an internal compound parietal layer. There is, in *Ceratozamia*, only a single macrospore mother-cell; and this does not divide, as in cryptogams; it produces the single macrospore, in the same way as the embryo-sac is in general formed. Shortly after the first appearance of the macrosporangium within the sporangiferous lobe, this latter produces, on its apex, turned towards the axis of the cone, two new formations, the nucellus and the integument. The nucellus owes its origin to one or two hypodermal layers of the macrosporangium; the integument is elevated on the lobe around the nucellus.

With regard to the homology of the parts—if *Ceratozamia* is to be taken as a normal type of the Cycadeæ, as seems most probable—the macrosporangium of Cycadeæ, developed within the sporangiferous lobe, is perfectly homologous to a sporangium of *Ophioglossum*; the nucellus and the integuments are new formations which find no homologue in cryptogams. In the Cycadeæ, therefore, neither the nucellus nor the ovule represents a sporangium; the sporangiferous

* 'Flora,' lxv. (1882) pp. 306–16 (1 pl.).
† See this Journal, *ante*, p. 648.
‡ Ann. Sci. Nat. (Bot.) xii. (1882) pp. 212–32 (7 pls.).

lobes must rather be compared to the "ovular mamelon" in angiosperms. The sporangiferous lobe, bearing the nucellus and the integuments, may be regarded as presenting the transition from the sporangium of *Ophioglossum* to the ovule of angiosperms.

Although the Cycadeæ are undoubtedly the most ancient phanerogams, and the most nearly allied to ·cryptogams, M. Treub does not consider it probable that any existing gymnosperms represent the actual transition from cryptogams to angiosperms; the forms we now have are probably derived from those which actually constituted the connecting link.

Cell- and Nuclear Division in the Formation of the Pollen of Hemerocallis fulva.*—According to E. Tangl, the young pollen mother-cells of *Hemerocallis fulva* have comparatively large finely granular nuclei, containing several nucleoli which are distinctly coloured by methyl-green or Beale's carmine. At a later period the number of nucleoli diminishes, so that each nucleus has only one or less often two, which are no longer coloured by methyl-green, while their colouring by Beale's carmine remains unchanged. At the same time the originally regular distribution of the granules is altered. They at first form a network, and afterwards a thin layer on the wall of the nucleus, with a larger central group, and an anastomosing network between them. To the hyaline substance between the granules Tangl applies Flemming's term, "intermediate substance." At this stage the structure of the nucleus is completely destroyed by alcohol; by treatment with acetic acid and methyl-green the granules are coloured a dark blue-green. At a later period the regularly distributed small granules of the nucleus are replaced by larger granular structures which behave in the same way towards reagents. Subsequently the nuclear membrane disappears, and the intermediate substance assumes a granular character, exactly resembling that of the surrounding protoplasm. This is followed by a new nucleus of irregular outline, destitute of membrane, and nearly entirely composed of granular substance which takes the pigment, and which is probably derived genetically from a coalescence of the granular structures with the nucleolus of the earlier nucleus. If two nucleoli are originally present, one of them appears not to take part in this coalescence, but to remain imbedded in the protoplasm. From the new nucleus is formed the nuclear plate, consisting in most cases of granules somewhat elongated in the direction of the axis of the spindle, less often of a continuous disk with teeth directed towards the pole, and lying in a clear hyaline portion of the protoplasm. The daughter-nuclei are at first roundish and finely granular; they subsequently change their form from unequal growth, their contents becoming at the same time differentiated into granules, intermediate substance, and membrane. The granules afterwards all lie on the membrane, on which they form a network with polygonal meshes. The formation of the nuclear plates in the secondary nuclei is preceded by a considerable diminu-

* Denkschr. K.K. Akad. Wiss. (Wien), xlv. (1882) 22 pp. (4 pls.). See Bot. Centralbl., xi. (1882) p. 169.

tion of the intermediate substance and of the entire volume of the nucleus. The cell-plates are formed in the same way as in other pollen-grains; but the arrangement of the daughter-nuclei differs somewhat from the normal, since they lie either in a plane or cross-wise. The special mother-cells sometimes undergo subsequent divisions, resulting in the formation of smaller pollen-grains.

Comparing this development with that of the animal ovum, the author considers the small globular structures or nucleoli, which often accompany the primary nucleus of the mother-cells when reduced by retrogressive metamorphosis, to be the homologue of the elements of the germinal vesicle which are not active in the formation of the bi-aster.

Structure and Growth of the Cell-wall.[*]—Professor E. Strasburger's most recent publication is divided into the following sections:—The origin and growth in thickness of the cell-wall; the growth of starch-grains; the relationship of swelling to anatomical structure; the formation of membrane in the animal kingdom; the double refraction of organized structures; the molecular structure of organized bodies; the assimilation of carbon; the function of the cell-nucleus; the permeability of the cell-wall; and the behaviour of the cell-nucleus in the process of sexual reproduction. The following are some of the more important results at which he has arrived:—

With regard to the intimate structure of organized bodies, Prof. Strasburger entirely dissents from Naegeli's micellar hypothesis. This hypothesis was based upon the phenomena of "swelling-up" which are so characteristic of organized bodies, and upon the optical properties which certain of these bodies possess. Professor Strasburger points out that swelling-up may be as well ascribed to the taking-up of water between the molecules of the body as to its being taken up between Naegeli's micellæ. He shows also that the double refraction of organized bodies, such as cell-walls and starch-grains, depends upon their organization as a whole; for when once their organization is destroyed, their double refraction is lost, a result which cannot be explained on the micellar theory, since the particles of the disintegrated micellæ would, like particles of broken crystals, still retain their power of double refraction. According to Strasburger the molecules of an organized body are not aggregated into micellæ which are held together by attraction, but are linked together, probably by means of multivalent atoms, by chemical affinity, in a reticulate manner. Swelling-up is then the expression of the taking-up of water into the meshes of the molecular reticulum, where it is retained by intermolecular capillarity. The more extensible the reticulum, that is, the more mobile the groups of molecules within their position of equilibrium, the greater the amount of swelling-up. The limit is reached when the chemical affinity of the molecules and the force of the intermolecular capillarity are equal; if the latter

---

[*] Strasburger, E., 'Ueber den Bau u. das Wachsthum der Zellhäute.' 264 pp. (8 pls.) Jena, 1882. Cf. also article by Dr. S. H. Vines in 'Nature,' xxvi. (1882) p. 595, and Bot. Centralbl., xi. (1882) pp. 269–83.

exceed the former at any moment, the result is the destruction of the molecular reticulum, or, in other words, of the organization. Protoplasm differs from other organized bodies in that the grouping of its molecules is undergoing perpetual change, the result of this molecular activity being the phenomena which we term vital.

The growth in thickness of cell-walls and of starch-grains takes place, according to Professor Strasburger, by the deposition of successive layers; in opposition to Naegeli's view, that the mode of growth was intussusceptive, with subsequent differentiation of layers. Even the surface-growth of cell-walls is not, in his opinion, intussusceptive, but is merely due to stretching.

With reference to the mode of formation of the cell-wall and of the thickening-layers, Strasburger agrees with the view of Schmitz that the cell-wall is formed by the actual conversion of a layer of the protoplasm, that is, chemically speaking, by the production of a layer of cellulose from a layer of proteid. When a mass of protoplasm is about to clothe itself with a membrane, the peripheral layer becomes densely filled with minute proteid bodies, the microsomata, and this layer then becomes converted into cellulose. The wall of a young wood-cell of *Pinus*, for instance, is clothed internally with a layer of protoplasm filled with microsomata, which are arranged in spiral rows; the microsomata then gradually disappear, and the layer of protoplasm is found to be replaced by a layer of cellulose, which presents spiral striation corresponding to the previously existing rows of microsomata, and which constitutes a thickening layer of the cell-wall. In cells the walls of which become much thickened, the whole of the protoplasm may be gradually used up in this way. Again, the wall of pollen-grains and of spores is formed from a peripheral layer of the protoplasm which contains abundant microsomata. Its subsequent growth, and especially the development of the asperities which it commonly presents, is effected by the surrounding protoplasm which is derived from the disorganized tapetal cells; this is especially well shown in the development of the epispore of *Equisetum* and of *Marsilia*. When an intine or endospore is present, it is produced like the outer coat from a peripheral layer of the protoplasm of the pollen-grain or spore. Further, the septum which is formed in the division of a cell is produced in the same way. The cell-plate, like the peripheral layer of the protoplasm of a young pollen-grain, contains microsomata which disappear, and it is then converted into a plate of cellulose. Finally, the successive layers of a starch-grain are produced by the alteration into starch of layers of proteid-substance derived from the starch-forming corpuscle (amyloplast).

Professor Strasburger next points out that the starch which makes its appearance in the chlorophyll-corpuscles under the influence of light, is derived from the proteid of the corpuscles by dissociation. The formation of this starch is therefore not the immediate product of the synthetic processes going on in the chlorophyll-corpuscles, but only a secondary product. The processes in question produce proteid. Professor Strasburger is inclined to accept Erlenmeyer's hypothesis, that methyl aldehyd is formed in the chlorophyll-corpuscles from

carbon dioxide and water, and to believe that by polymerization a substance is produced which can combine with the nitrogenous residues of previous dissociations of proteid to reconstitute proteid. He does not agree with the suggestion of Loew and Bokorny that the methyl aldehyd may combine with ammonia and sulphur to form proteid *de novo*.

Lastly, Professor Strasburger makes a suggestion as to the probable physiological significance of the nucleus. He points out that the nucleus cannot be regarded as regulating cell-division; for instances are known of cell-division taking place without previous nuclear division, and, conversely, of nuclear division taking place without cell-division. He is of opinion that the nucleus plays an important part in the formation of proteid in the cell. This view is founded upon the facts that one or more nuclei have been found to be present in the vast majority of plant-cells, that the nucleus is, as a general rule, the most persistent protoplasmic structure, and that it gives the various proteid reactions in a very marked manner.

Order of Appearance of the Primary Vessels in Aerial Organs.[*] —A. Trécul has collected the results of a long series of observations on the formation of the first vessels in the stem, leaves, and floral organs of the following plants :—*Anagallis arvensis, Primula elatior, officinalis, grandiflora,* and other species, *Lysimachia, Ruta, Lupinus, Astragalus, Galega officinalis, Fœniculum vulgare* and *dulce, Iris, Allium, Funkia, Hemerocallis,* and a number of grasses. For the details of the observations reference must be made to the paper itself. Among the more important of the general results, M. Trécul is led to contest the usual statement that all stems and leaves branch from below upwards, and especially Sachs' explanation of the pinnate and other forms of division in leaves as referable to a scorpioid type. The order of appearance of the vascular bundles shows, on the contrary, that there are two kinds of pinnate leaves, basifugal or acropetal, and basipetal; and the same is true of leaves where the segmentation is not carried so far; and also of the secondary divisions of the leaflets themselves. The basipetal development may also be altogether independent of any scorpioid arrangement.

Collenchyma.[†]—An examination of the structure and mode of formation of collenchyma in a large number of plants, made by C. van Wisselingh, confirms the general statement of Sachs, that this tissue has its origin directly in the fundamental tissue. In all the plants examined by him the vascular bundles were already in existence in the procambial condition before the formation of the collenchyma. He found no instance of the common origin of collenchyma and mestome described by Haberlandt and Ambronn. The number of layers of cells found in the youngest state between the epidermis and vascular bundles varied from two to six, or even more.

Most commonly, in the tissue intermediate between the epidermis

[*] Ann. Sci. Nat. (Bot.) xii. (1882) pp. 251–381.
[†] Arch. Néerland. Sci., xvii. (1882) pp. 23–58 (2 pls.). Cf. this Journal, i. (1881) p. 768.

and vascular bundles, cell-division plays, in the first place, the most important part, and afterwards the collenchymatous thickening ; more rarely the two processes are simultaneous. The period when the thickening begins to manifest itself prominently depends on the mechanical function which the collenchyma has to fulfil in the young organs of the plant.

It is not uncommon for the thickening of the cell-walls to be accompanied by rounding off and disappearance of the intercellular spaces.   The septated collenchymatous fibres, which terminate at the extremity of the stem in *Lamium purpureum* and *Aesculus japonica* proceed from parenchymatous cells.   Haberlandt found, on the contrary, that in *Lamium purpureum, Atherurus ternatus, Cucurbita Pepo,* and *Tradescantia erecta,* the fibres originate from a generating prosenchymatous tissue formed by repeated longitudinal division of merismatic mother-cells.   In *Chenopodium album* the same observer always found collenchyma originating from parenchyma.

In none of the plants examined was the author able to detect a closer genetic connection between the cells of the collenchyma themselves than between them and the adjacent parenchymatous cells. Sanio, on the contrary, states, in the case of *Euonymus latifolius* and *Peperomia blanda,* and Haberlandt in that of *Tradescantia erecta,* that the collenchyma is derived from a single hypodermal layer of cells.

Stomata in a Fossil Plant.[*]—In a large series of fossil plants obtained from the Turonian beds of the cretaceous formation from the neighbourhood of Bagnois (Gard) R. Zeiller finds very well-preserved wood of a conifer closely allied to the *Thuyites Hoheneggeri* Ettings. of the Wealden.   In the ultimate branches or leaves, the stomata may be exceedingly well made out ; and they are remarkable for having, instead of a single fissure, an opening in the form of a star with four or five rays.   The stomata are formed of four, or less often of five cells arranged in a rosette, the walls of which radiate towards a central point, but leaving an orifice in the centre, in length about one-third or two-fifths of the rays.   The mechanism by which the opening is produced is the same as in ordinary stomata, except that four or five cells instead of two share in it.   The stomatic orifice occupies the bottom of a slight depression, though not so well marked as in the allied recent *Callitris quadrivalvis, Libocedrus decurrens,* and *Frenela,* and are usually surrounded, as in them, by a slightly projecting margin of cuticle.   The stomata are arranged regularly in rows over the whole surface of the leaf.

Spiral Cells in Crinum and Nepenthes.[†]—A. Trécul and L. Mangin both describe, as the result of separate investigations, the large spiral cells found by the first in several species of *Crinum,* by the last also in *Nepenthes phyllamphora.*   In *Crinum americanum* they are dispersed through all parts of the parenchymatous tissue of both faces of the leaf, into the immediate neighbourhood of the large inter-

[*] Bull. Soc. Bot. France, xxviii. (1881) pp. 210–4.
[†] Ann. Sci. Nat. (Bot.) xiii. (1882) pp. 200–7 and 208–16 (1 pl.).

cellular spaces, and of the fibro-vascular bundles, usually collected together into groups, often in long longitudinal bundles. They are greatly elongated cells, from 0·5 to even 13 mm. in length, and from 0·025 to 0·06 mm. in diameter, and occasionally are even branched. They contain nothing but air, and are surrounded by ordinary parenchymatous cells. Their form and disposition differ in other species of *Crinum*, but are nearly uniform in the same species. They were not found by M. Trécul in any part of the plant except the leaves; but M. Mangin finds them also in the cortical tissue of the stem, where they attain a still greater size. M. Mangin considers them as analogous to internal hairs.

In *Nepenthes phyllamphora* similar cells occur in the stem, the leaves, and the pitchers, but always isolated. The parenchyma which contains them is here compact, and not furnished with intercellular passages.

Structure of Secretory Glands.*—An examination of the internal glands in a large number of plants has led Dr. F. R. v. Höhnel to the following general results :—

The glands of the Myrtaceæ, those Leguminosæ which were examined (*Amorpha*, *Hymenea*, and *Trachylobium*), the Hypericineæ (*Hypericum* and *Androsæmum*), and of *Oxalis, Lysimachia, Myrsine, Ardisia*, and *Peganum Harmala* are schizogenous; while (except *Peganum Harmala*) those of the Rutaceæ and their allies (*Callionema, Citrus, Toddalia, Boronia, Correa,* and *Ptelea*) are lysigenous.

The secretion-cavity is always completely closed in lysigenous glands : while in schizogenous glands there are three distinct varieties :—(1) completely closed, which is the ordinary case ; (2) those which at length burst from the copious excretion of fluid (*Oxalis floribunda*) ; and (3) altogether open ; these are properly only secretory portions of ordinary air-containing intercellular spaces (*Peganum Harmala* and *Lysimachia ephemera*).

Glands which are buried in the tissue are either entirely dermatogenous (*Amorpha*, and those Myrtaceæ where the glands are immediately beneath the epidermis), or are in their outer portion formed out of the epidermis (*Citrus, Dictamnus*, and probably *Correa, Toddalia,* and many other genera of Rutaceæ), or their origin is altogether independent of the epidermis (all deeply buried glands, as those of *Eucalyptus, Hypericum, Ardisia, Myrsine,* &c.). Lysigenous glands appear to be generally formed from several cells which have become separated before the first appearance of the gland (*Callionema* and *Citrus*) ; while schizogenous glands are almost always formed from a single cell (Myrtaceæ, *Lysimachia, Hypericum,* and *Myrsine*), very seldom from several (*Amorpha*).

When mature the distinction between schizogenous and lysigenous glands is always observable. The former always have an epithelium sharply defined on the inside, and usually more or less clearly distinguishable from the surrounding cellular tissue by the nature of the cell-wall and of the cell-contents ; it is from this that the fluid

---

* SB. K.K. Akad. Wiss. (Wien), lxxxiv. (1881) pp. 565–603 (6 pls.).

is excreted, and it is entirely wanting in lysigenous glands; the latter are usually surrounded by partially absorbed cells which are not sharply distinguishable from the surrounding tissue.

In glands which originate from the epidermis (*Amorpha*, *Myrtus*, and *Eugenia*), it is not uncommon that instead of growing into the parenchyma, they become glandular, warty, or conical trichomes; which appears to indicate that internal epidermal glands originate as trichomic glands; the latter being phylogenetically the older.

The schizogenous glands of *Hymenea* and *Trachylobium* contain copal; the hard copal of *Trachylobium* having undoubtedly a similar origin. In *Ardisia crenulata* are peculiar schizogenous secretory organs, formed locally out of the medulla of the veins of the margin of the leaf, and which contain an albuminoid substance; of these a careful examination was made. The same species also possesses secretory organs, which from their origin and structure must be regarded as a coalescence of secretory tubes.

The mucilage-tubes of *Abies* possess albuminoid crystalloids in the interior of the mass of mucilage formed in the protoplasm. A description is given also of the origin, structure of the wall, and nature of the contents of the secretory tubes of *Evodia glauca*, *Rhamnus*, *Æonium tortuosum*, *Mesembryanthemum*, *Physostegia virginiana*, *Calycanthus*, *Cœsalpinia echinata*, &c. Oil and mucilage-tubes also occur in the wood of some Laurineæ.

Sphero-crystals.[*]—G. Kraus records the discovery of sphero-crystals in *Ptelea trifoliata*, *Conium maculatum*, and *Æthusa*, apparently identical in composition with those previously detected in *Cocculus laurifolius*. In *Ptelea* they occur in the leaf only; in *Conium* also in the stem, flower-stalks, fruits, &c.; but in all cases in the epidermis only. They usually have the form of hemispheres attached to the wall; and are radiate or even spined. As in *Cocculus*, they are not found in every epidermal cell, but in groups in adjoining cells, and attached to the adjacent transverse walls. They are insoluble in cold or boiling water, and in dilute mineral or organic acids; soluble in concentrated sulphuric acid with a golden yellow colour, and in potash-ley or hot nitric acid. The reactions indicate a probability that they are composed of hesperidin. Their insolubility in alcohol shows that they cannot consist of any compound of conia.

Respiration of Detached Shoots.[†]—It is an established fact that a sprig of a plant, if placed for some hours in an atmosphere of carbonic acid and then removed and placed in the dark, exhales a more than normal amount of carbonic acid. This has been stated to be due simply to the giving up of carbonic acid which has been taken in in excess, but not assimilated. J. Borodin combats this conclusion with the following arguments:—

The activity of respiration of a detached twig is not constant, even when the conditions are constant; it becomes less in the dark. This

---

[*] Ber. Naturf. Ges. Halle, 1881, pp. 41–3.
[†] Mem. Acad. Imp. Sci. St. Petersbourg, xxviii. (1881) No. 1. Cf. Naturforscher, xiv. (1881) p. 463.

diminution is due to gradual exhaustion of the supply of carbo-hydrates, for if carbo-hydrates are assimilated afresh the activity of respiration takes a new start.

That this renewed activity is caused by assimilation and not by simple absorption of carbonic acid is shown by the fact that (1) both light and carbonic acid are necessary to the commencement of this condition ; (2) insolation is useless without carbonic acid ; (3) an atmosphere rich in carbonic acid is useless without light ; (4) a small proportion of carbonic acid is sufficient, if combined with light ; (5) absorption of oxygen undergoes increase after insolation ; (6) the intensity of the light is of importance ; sunlight is best ; (7) the more refrangible rays take part in the action.

Absorption of carbonic acid may take place to a slight extent, in addition to the assimilation ; but it only occurs after a sojourn in a richly carbonized atmosphere, and it passes off in from one to two hours. The solid parts take an active part in the absorption ; seeds apparently absorb as much (in relation to their weight) in a dry as in a soaked state. Dry seeds absorb only insignificant quantities of hydrogen.

Physiological Functions of the Tissues of Plants.*—G. Haber-landt occupies a section of Schenk's 'Handbook of Botany' ('Encyklo-pædie der Naturwissenschaften') with an exhaustive account of the various kinds of vegetable tissue, and of the parts which they fulfil in the economy of the plant ; treating the subject from a Darwinian point of view, i. e. regarding the anatomical structure and arrange-ment of tissues as a series of phenomena of adaptation. The following is his classification of tissues :—

    I. Epidermal System.
        1. Epidermis.   2. Cork.   3. Bark.
    II. Skeletal System.
        1. Bast and libriform.   2. Collenchyma.   3. Scleren-
           chyma (?).
    III. Nutritive System.
        1. Absorptive System (Epithelium of the root, root-
           hairs, &c.).
        2. Assimilative System (Chlorophyll-parenchyma ; pali-
           sade tissue).
        3. Conductive System (Conducting parenchyma ; con-
           ducting bundles [mestome, hadrome, leptome] ;
           parenchyma-sheaths ; laticiferous vessels).
        4. Aerative System (Tracheal System (?) ; air-conducting
           intercellular spaces with their orifices [stomata and
           lenticels]).
      Local structures.   Endoderm ; thickened vascular bundle-
        sheaths ; glandular, oil-, mucilage-, and gum-passages, &c.

The following definitions are also given : *Protoderm* consists of

---

the peripheral layer of merismatic cells; *Cambium* of parenchymatous cells with narrow cavity, usually united into longitudinal bundles; *Fundamental parenchyma* is the tissue which remains after the differentiation of the protoderm and cambium.

Chlorophyll and Hypochlorin.*—A. Tschirch gives the following as the results of a series of fresh observations on chlorophyll and its derivatives.

Pringsheim's hypochlorin (at all events as regards the greenish yellow needles) is a product of the action of acids on the colouring matter of chlorophyll, and can be produced outside the plant in the well-known crystals. To distinguish this from the possible colourless matrix, which has, however, not yet been satisfactorily separated, the author calls it α-hypochlorin. It is identical with Hoppe-Seyler's chlorophyllan, and with the precipitate which appears spontaneously when solutions of chlorophyll have stood for some time. All the substances belonging to this group are products of oxidation of a portion of the chlorophyll. Chlorophyllan, or α-hypochlorin, can easily be obtained pure in the form which Pringsheim has described, by laying leaves of grass which have been freed by ether from oil and wax, for some days in hydrochloric acid, carefully washing out the acid, and extracting with boiling alcohol. When the filtrate cools abundance of α-hypochlorin precipitates, which can be increased by distilling off a portion of the alcohol. It crystallizes in the form of dark brown (or greenish in incident light) radiating needles; the whip-like form results from the impurity of the solution.

The formation of chlorophyllan in the living plant is due to the presence of organic acids. With the exception of water-plants, the author found none in which the cell-sap has not a distinct acid reaction. When the proportion of acid is only small, the chlorophyllan is only formed by allowing the extract to stand for a long time; carbonic dioxide produces it at once. The extracts of strongly acid leaves like those of *Aesculus* or *Rumex*, deposit chloryphyllan simply on cooling. The formation is completely prevented by giving an alkaline reaction to the extract.

It is probable that many of the described modifications of chlorophyll depend on the variation in the proportion of acid present in the cell-sap, and in the variable solubility of the acids in the solvents employed.

The cause of the absence of hypochlorin from the chlorophyll-grains in many plants, even when lying in an acid cell-sap, is the fact which Tschirch has established, and which had already been assumed on theoretical grounds by Naegeli and Pfeffer, that every grain of chlorophyll is surrounded by a colourless hyaloplasmic layer, which may frequently be clearly made out, especially in water-plants. In the living state this hyaloplasmic layer is not permeable to acids; it is consequently only after death that the acid cell-sap enters and produces α-hypochlorin.

In a subsequent communication Tschirch further criticizes Prings-

---

* SB. Bot. Ver. Prov. Brandenburg, 1882, pp. 41-5, 124-34.

heim's arguments, and agrees with his conclusion that the first product of assimilation must be a substance containing less oxygen than had previously been supposed. There is also a good deal in favour of the view that this substance is Pringsheim's hypochlorin; but on the whole the author considers it more probable that it is a product of decomposition of the colouring matter of the chlorophyll, formed only on the addition of reagents. The statement of Pringsheim that " in those cases where the chlorophyll-grains assume large dimensions, as in bands, plates, &c., it is easily seen that the hypochlorin does not appear everywhere where there is colour, but is localized to certain spots," is not confirmed by Tschirch's observations.

Function of Chlorophyll.[*]—Professor N. Pringsheim's latest contribution to this subject is chiefly occupied with an historical *résumé* of our knowledge, and a reply to objections from various sources to his previously published views, to which he adheres in all essential points. Pringsheim does not agree with the view of some other investigators [†] that the first product of assimilation is formic aldehyde. This is not in accordance with the fact that in the light the volume of oxygen evolved is equal to that of carbon dioxide decomposed, taken into consideration in connection with the simultaneous respiration of the plant. The total result can only be explained by the product of assimilation being a compound which contains a smaller proportion of oxygen than formic aldehyde.

Vitality of the Chlorophyll-pigment.[‡]—G. Kraus preserved fruits of *Cucurbita melanosperma* in an ordinary sitting-room for more than three years, at the end of which time mould began to appear on them. The non-chlorophyllaceous cells were then found to contain protoplasm and other cell-contents apparently unchanged. In the chlorophyllaceous cells, on the other hand, the chlorophyll-grains were transformed into green balls, having undergone a change similar to that of the autumn colouring of the leaves of the horse-chestnut. The colouring-matter of the chlorophyll appeared, however, to be entirely unchanged. An alcoholic extract gave the typical spectrum of chlorophyll with seven bands.

Action of various Gases on Plants.[§]—W. Detmer has experimented on the influence of various gases on living plants. He found the effect of nitrous oxide, hydrogen, and carbonic acid to be very similar, hindering the further development of seeds and seedlings, and preventing heliotropic curvatures and the greening in the light of etiolated parts of plants. Chloroform also acted disadvantageously on growth; but respiration was not suspended in an atmosphere containing much chloroform.

Power of Plants to absorb Carbonic Oxide.* — L. Just has subjected *Azolla caroliniana* and *Lemna gibba* to a series of experiments for the purpose of determining whether plants can assimilate CO in the place of CO_2. He finds that this gas is not absorbed by green plants; but that it is injurious only when its proportion in the atmosphere exceeds 10 per cent. It then prevents the formation of chlorophyll, and hinders assimilation and growth. If the gas is then removed, the plant may partially recover. Chlorophyll-grains have no power of absorbing carbonic oxide. Control-experiments were also made on the same plants under the same circumstances with pure air entirely free from carbonic acid gas and with air containing the normal amount of this gas.

Formic Acid in Plants.†—In addition to the somewhat doubtful occurrence of free formic acid in the stings of the stinging-nettle and similar structures, A. Vogel records an undoubted instance in a powder which occurs in commerce made from the hairs of *Negretia pruriens*. The quantity, however, is very small, and the author thinks that, both in this case and in that of the irritating fluid of the stinging-nettle, the irritation is partly mechanical, due to the large amount of silica present in the part of the hair which enters the wound.

The presence of formic acid in the vegetable kingdom is easily explained by the oxidation of albuminoids and of carbonic acid, and by the action of oxalic acid on glycerine. In addition to the stinging-nettle, it has been detected in the leaves, bark, and wood of the spruce fir, in the sap of the house-leek (*Sempervivum tectorum*), and in the fruits of the tamarind, and of *Sapindus Saponaria*. Its well-known occurrence in honey, where it is accompanied by other vegetable acids, probably lactic, malic, and oxalic acids, is due to its excretion from the stinging-gland of the bee. The proportion present in new sugar averages about 1 per cent. It has the effect of hindering fermentation, and hence promoting the preservation of the honey.

Function of Lime-salts.‡—H. de Vries points out that there is hardly any experimental evidence in support of the ordinary theory of the part played in the life of the plant by calcium oxalate, viz. that the oxalic acid is a product of the albuminoids, and that its function is to decompose the calcium phosphate and sulphate, the lime being the carrier of phosphoric and sulphuric acids to the plant. On the contrary, the formation of albuminoids and of calcium oxalate appears to go on quite independently of one another, while protoplasm has an alkaline reaction, and cannot therefore contain free phosphoric or sulphuric acid.

The fact that the amount of lime deposited in the leaves increases continually with their age appears to point to the conclusion that it is an excretory product. The ordinary theory that calcium oxalate

* Forsch. aus dem Geb. der Agriculturphysik, v. p. 60. See Naturforscher, xv. (1882) p. 336.

‡ Vries, H. de, ' Ueber die Bedeutung der Kalkablagerungen in den Pflanzen. 34 pp. (Berlin, 1881). See Bot. Centralbl., x. (1882) p. 194.

is insoluble in the cell-sap does not rest on a satisfactory basis; in some cases, on the contrary, it would certainly appear to be dissolved, and in this state to pass through the cell-wall. It is, however, soluble with difficulty; and the function of oxalic acid seems to be to get rid, in this form, of what would otherwise be an injurious excess of lime. Lime and oxalic acid are both present in soils in greater quantity than is needed by the plant; and their excess is consequently excreted by the plant in an insoluble form, or at least one that is soluble only with difficulty.

Function of Resinous Substances.[*]—H. de Vries has investigated this subject in detail, especially in reference to the terebenthin and resin produced by conifers; and urges arguments in opposition to the generally accepted view that these substances are simply waste products of an excretory nature. Terebenthin is the substance most rich in carbon which occurs in conifers, and its production requires, in consequence, the consumption of a relatively large quantity of assimilated substances, especially of glucose, from which it is probably formed only by a long series of chemical transformations; and its production can in no sense be regarded as analogous to that of gum in wounded cherry or plum trees. It must, on the contrary, be looked on as a normal and important function in the life of conifers. As long as the reservoirs in which it is formed remain closed, this resin undergoes no change; but whenever the organ is wounded, it flows out in the form of a thick viscid mass, which gradually hardens on exposure to the air. But it not only spreads over the surface of the wound, it penetrates also to the interior of the wood, fills the cell-cavities, and saturates the cell-walls.

According to their direction, the resin-canals of the wood and bark of conifers may be classified into horizontal and vertical; the former are found especially in the medullary rays.

Briefly, the object attained by conifers in sacrificing so large a quantity of food-material in the production of resinous secretions, is the acquisition of a substance which furnishes a complete remedy against a great variety of injuries to which the woody tissues are subject.

The author then investigates the functions of similar secretions formed by other orders of plants, especially that of resinous substances, gums, and latex. The entire absence of substances of this nature in large groups of plants, as the Palmæ, Cyperaceæ, Gramineæ, and the greater number of Cruciferæ and Ranunculaceæ, indicates that their function must have relation to special circumstances. That the function of all these substances is similar is further indicated by the fact that they replace one another in different plants or groups of plants, it being very unusual to find more than one kind in the same species. Again, under normal conditions, they are never resorbed out of their reservoirs to take part in other nutritive processes; as long as they remain in their reservoir they are completely inactive. In this situation they are always subject to a certain pressure which

causes them to flow over the surface of the wound when the reservoir is injured.

All the substances produced by the hardening of latex and the other resinous fluids in contact with the air, resin, caoutchouc, wax, &c., are glutinous, and are admirably adapted for the protection and healing of wounds. On escaping from their receptacle they are decomposed into two parts, a thin liquid fluid, and the thick mucilaginous substance which was previously dissolved in the first. Their function, in fact, appears to be identical with that of the resin and terebenthin of conifers. One of the injurious results of wounds which they prevent is the settlement and germination in the exposed tissue of the wounded part of the spores of parasitic fungi.

In plants and organs of the simplest structure, such as Thallophytes, mosses, and the prothallia of ferns, the process of recuperation after a wound is simply that the injured cells die and are not replaced, the uninjured cells in contact with them carrying on the life of the individual. In plants of higher organization, on the contrary, the injured tissue must be replaced by a freshly formed tissue, which process is carried on under the protection of these resinous secretions. This new tissue is of the nature either of callus or of traumatic bark, both resulting from the segmentation of cells by cell-walls parallel to the surface, new layers being formed in this way, the walls of whose cells are subsequently impregnated with suberous matter.

Change of Starch into Sugar at low temperatures.[*]—H. Müller-Thurgau has experimented on the sweetening of potatoes by frost, depending on the conversion of starch into sugar. He finds that it depends on the freezing taking place slowly, and on the temperature sinking to at least − 3° C. When once begun the process goes on rapidly. Different kinds of potatoes exhibit very different properties in this respect, and the presence of a large amount of water promotes the sweetening. The transformation is occasioned by a diastatic ferment, the propagation of which is promoted by a low temperature.

Colours of Flowers.[†]—In an article by Grant Allen, on "The Colours of Flowers, as illustrated in the British Flora," the author says that the different hues assumed by petals are all, as it were, laid up beforehand in the tissues of the plant, ready to be brought out at a moment's notice. And all flowers, as we know, easily sport a little in colour. But the question is, Do their changes tend to follow any regular and definite order? Is there any reason to believe that the modification runs from any one colour towards any other? Apparently, there is. All flowers, it would seem, were in their earliest form yellow; then some of them became white; after that, a few of them grew to be red or purple; and, finally, a comparatively small number acquired various shades of lilac, mauve, violet, or blue.

Some hints of progressive law in the direction of the colour-change from yellow to blue are sometimes afforded us even by the

---

* Naturforscher, xv. (1882) pp. 349-51.

† Allen, Grant, 'The Colours of Flowers as illustrated in the British Flora.' 119 pp. (8vo, London, 1882.) Cf. Bull. Torrey Bot. Club, ix. (1882) pp. 117-8.

successive stages of a single flower. For example, one of our common little English forget-me-nots, *Myosotis versicolor*, is pale yellow when it first opens; but as it grows older, it becomes faintly pinkish, and ends by being blue, like the others of its race. Now, this sort of colour-change is by no means uncommon; and in almost all known cases it is always in the same direction, from yellow or white, through pink, orange, or red, to purple or blue. Thus one of the wall-flowers, *Cheiranthus chamœleo*, has at first a whitish flower, then a citron-yellow, and finally emerges into red or violet. The petals of *Stylidium fruticosum* are pale yellow to begin with, and afterwards become light rose-coloured. An evening primrose, *Œnothera tetraptera*, has white flowers in its first stage, and red ones at a later period of development. *Cobœa scandens* goes from white to violet; *Hibiscus mutabilis* from white, through flesh-coloured, to red. The common Virginia stock of our gardens (*Malcolmia*) often opens of a pale yellowish green, then becomes faintly pink, afterwards deepens into bright red, and fades away at last into mauve or blue. Fritz Müller noticed in South America a *Lantana*, which is yellow on its first day, orange on the second, and purple on the third. The whole family of *Boraginaceœ* begin by being pink, and end by being blue. In all these, and many other cases, the general direction of the changes is the same. They are usually set down as due to varying degrees of oxidation in the pigmentary matter.

If this be so, there is a good reason why bees should be specially fond of blue, and why blue flowers should be specially adapted for fertilization by their aid; for bees and butterflies are the most highly adapted of all insects to honey-seeking and flower-feeding. They have themselves, on their side, undergone the largest amount of specialization for that particular function. And if the more specialized and modified flowers, which gradually fitted their forms and the position of their honey-glands to the forms of the bees or butterflies, showed a natural tendency to pass from yellow, through pink and red, to purple and blue, it would follow that the insects which were being evolved side by side with them, and which were aiding at the same time in their evolution, would grow to recognize these developed colours as the visible symbols of those flowers from which they could obtain the largest amount of honey with the least possible trouble. Thus it would finally result that the ordinary unspecialized flowers, which depended upon small insect riff-raff, would be mostly left yellow or white; those which appealed to rather higher insects would become pink or red; and those which laid themselves out for bees and butter-flies would grow for the most part to be purple or blue. Now, this is very much what we actually find to be the case in nature.

Causes of the Etiolation of Plants.*—E. Mer points out that the aquatic forms of amphibious plants present, in their external appearance and internal structure, a close analogy with the forms of aerial plants grown in the dark or in moist air. A comparison of these phenomena shows that etiolation is the result of a variety of

* Comptes Rendus, xcv. (1882) pp. 487-9.

causes of different importance acting together or separately. When the stem is rudimentary or reduced to a bulb, and the leaves are sessile, the nutritive equilibrium exercises only a feeble influence, since the nutritive materials are all collected in one organ; the relative dimensions only of this organ are modified. The most complex case is where the causes of etiolation combine, as when an aquatic plant, furnished with a stem and petiolate leaves, is immersed in the dark, as occurs in the first leaves of water-plants growing at a great depth.

Origin of Galls.* — In opposition to the view of Dr. Adler, J. Paszlavszky has established that all rose-galls arise in leaf-buds which have been punctured by *Rhodites rosæ*. The female works in three directions corresponding to the phyllotaxis of the rose, laying her eggs, which are provided with a long stalk, on the three leaves which constitute a whorl.† All galls become in this way circular by the shortening of the internodes. All terminal galls are originally circular, and have become terminal by the gradual withering of the leaves from the apex downwards. The ultimate form of the gall depends greatly on the number of larvæ that develope within it.

B. CRYPTOGAMIA.
Muscineæ.

Male Fructification of Polytrichum.‡—K. Goebel investigates the phenomena connected with the habitual prolification of the antheridial receptacle or male fructification of *Polytrichum*.

He finds that Leitgeb's rule, derived from the case of *Fontinalis*, that the first antheridium springs from the apical cell, and is the termination of the primary axis, is not of general application. In *Polytrichum*, on the contrary, the large apical cell of the primary axis may be recognized in the middle of the fructification; the first antheridium cannot therefore proceed from it. From each leaf-forming segment beneath the leaf springs a group of antheridia. It follows from this that the antheridia which form a group do not stand at the same height, but are arranged in two or three superposed rows. Among them stand a great number of densely packed paraphyses, which, together with the somewhat modified leaves, completely enclose the antheridia. A leaf is produced of each segment of the apical cell. The growing point of the stem is not, as in *Fontinalis* and other genera, slender, but flattened, somewhat as in *Lycopodium Selago*. At a later period, when the antheridia are mature, the growing point even lies in a cup-shaped depression. The flattening of the growing point is caused by the growth of each segment being stronger in its upper portion nearest the surface of the stem than in its lower part. From the base of the young leaves hairs spring at an early period on the side which faces the apical cell; antheridia have never been observed in this position.

---

* *Naturforscher*, xv. (1882) p. 308.

† The phyllotaxis of the rose is 2–5, five leaves making up two whorls.—ED.

‡ *Flora*, lxv. (1882) pp. 323–6 (1 pl.).

The development of the separate antheridia agrees with that of *Fontinalis*; they have a 2-edged apical cell, which produces two rows of segments. The youngest stage shows two inner cells surrounded by a number of parietal cells. The further arrangement of the cells in subsequent divisions probably differs in different genera.

It follows from what has been said, that in *Polytrichum*, the antheridia do not, as is generally stated, stand in the axils of the leaves, and that their arrangement differs from what has been previously observed. While in *Fontinalis* and other genera of mosses, the antheridia differ in their place of origin, the first springing from the apical cell, the next in place of the leaves, the subsequent ones having no definite point of origin, in *Polytrichum* all the antheridia have the same origin, viz. beneath the leaves from outer cells of the tissue of the stem which belong to the same segment as the leaf. This fact furnishes another illustration of the general law that the place of origin of an organ does not determine its morphological value.

Fungi.

Epiplasm of Ascomycetes—Glycogen of Plants.[*]—The following are the principal conclusions of Dr. L. Errera on this subject, the method adopted for extracting glycogen from fungi and other plants being that of Brücke,[†] slightly modified in some cases.

1. Glycogen or "animal starch" exists not only amongst the animals in which Claude Bernard discovered it, and in the Protista (where it was first pointed out by Kühne), but is also found in plants.

2. Many of the ascomycetous fungi contain it in their tissues and in their asci. *Pilobolus*, and, almost certainly, the yeast of beer, equally contain it. The identity of the glycogen of *Peziza vesiculosa* (which the author has studied most in detail) with the glycogen of the liver of Mammalia is complete.

3. The epiplasm of the asci of Ascomycetes, suspected by Tulasne and described by de Bary, is formed of a spongy mass, probably albuminous, completely permeated with glycogen.

4. Even outside the fungi, all the plants studied (*Lemanea, Linum, Mahonia, Solanum*) contain substances at least analogous to glycogen, non-nitrogenous, giving more or less opalescent aqueous solutions which turn more or less brown with iodine, having no reducing action whatever on the cupro-alkaline reagents, but becoming transformed into reducing bodies by boiling with dilute sulphuric acid.

5. There also exist reducing substances analogous to the dextrines in the aqueous extracts of several plants (*Tuber, Agaricus, Solanum*); in others they have not been found (*Peziza, Lemanea*).

6. When it is not in too small a quantity the glycogen may be

---

[†] SB. K.K. Akad. Wiss. (Wien), lxiii. (1881) p. 214; and Vorles. über Physiol., i. (1881) p. 324.

determined by microchemical means, by its appearance, by its semi-fluid consistency, by the absence of reaction with osmic acid, Millon's reagent, and the salts of iron, by its solubility in water, and by its assuming with iodine a mahogany-brown or brown-red colour, which dissipates with heat and reappears on cooling. The proteid substances, on the contrary, become yellow rather than brown with iodine, and this colour is not diminished by moderate heating.

7. The glycogen of the Ascomycetes, at first diffused throughout the whole of the young plant, as it is in the animal kingdom in the fœtus, soon accumulates in the asci in considerable quantity, and disappears gradually as the spores ripen.

8. It is utilized in the development of the spores. Besides its eventual function of a respiratory reserve, there are good reasons for supposing that in the truffles, and probably also in other Ascomycetes, it furnishes materials for the formation of the oil of the ripe spores.

9. Around glycogen and starch are ranged some allied substances. It is thus that we are led to place in contact to one another a *glycogen group and a starch group.* We may, with Boehm and Hoffmann, rank with the former the glycogen of the liver and that of the muscles, xantho-glycogen, achro-glycogen, and glycogen-dextrin ; and among the latter, starch, the amylo-dextrins, and inulin.

10. Glycogen, glycogen-dextrin, starch, amylo-dextrin, and inulin do not give true solutions with water ; they only form a kind of magma, more or less thin, in which the greater portion of the substance is mechanically suspended. This fact helps us to understand the storing up of glycogen and inulin in particular cells.

Agaricini.[*]—In a review of our present state of knowledge of the Agaricini, S. Schulzer holds that the generic classification of *Agaricus* according to the colour of the spores, though not a natural classification, is the most convenient at present proposed. The division into subgenera is not so satisfactory ; and he adduces several instances in which a series of forms belonging to the same species must be placed some in one and some in another subgenus.

With regard to the genera of Agaricini outside *Agaricus,* he considers that there is no sufficient distinction between *Cantharellus* and *Craterellus,* nor between *Panus* and *Lentinus. Marasmius* also should be united with *Agaricus.*

Development of Sclerotium of Peziza Sclerotiorum.[†]—Correcting some mistakes in the account previously given by Brefeld and Coemans, O. Mattirolo gives the following description of the mode in which the cup of *Peziza Sclerotiorum* is formed out of the sclerotium :—

The sclerotium varies greatly in form ; but a cortical layer from two to four cells in thickness can always be distinguished from the medullary portion. The first rudiments of the cup make their appearance in the outer medullary layers. The hyphæ divide and become

[*] Oesterr. Bot. Zeitschr., xxxii. (1882) pp. 186-9, 220-5, 250-3.
[†] Nuov. Giorn. Bot. Ital., xiv. (1882) pp. 200-12 (2 pls.).

closely entangled, but without an ascogonium being distinguishable; a small endogenous ball of slender hyphæ being thus formed, which continues to increase in size, and finally bursts through the cortical layers which have bulged out into a spherical form. From this ball a string of hyphæ grows upwards, surrounded by a cylinder of thicker hyphæ derived from the detached outer medullary layers of the sclerotium. These outer coarser hyphæ form the cortical layer of the cup, the inner bundle developes into the medullary layer of the stalk, and later into the hymenium. The body thus formed is at first cylindrical; the cortical hyphæ diverge at their distal end, and thus form a club-shaped structure; while the finer central hyphæ converge distally. In the middle of the bundle the hyphæ cease after a time to increase in length; while the outer ones continue to grow, and thus form an elongated cylinder. The wall of this canal is clothed with the ascogenous ends of the hyphæ. At a later period the canal becomes wider above, becoming first funnel-shaped and the margin then expanding flat, thus forming the well-known cups of *Peziza Fuckeliana*. At first paraphyses only are visible on the disk; the asci are first formed in the centre, and gradually extend to the margin. Usually several are formed on the thickened end of each hypha; but the ascogenous hyphæ appear to have the same origin as the sterile ones which become paraphyses.

Development of the Sporangia of the Phycomycetes.[*]—M. Büsgen describes the mode of development of the sporangia and of their zoospores in the following genera of Phycomycetes :—*Dictyuchus, Leptomitus, Saprolegnia, Achlya, Aphanomyces, Phytophthora, Cystopus, Pythium, Peronospora,* and *Mucor.*

These exhibited several distinct modes of spore-formation. In some cases a number of spores are developed within the sporangium to more or less complete isolation. In these cases cell-plates are formed, the entire contents of the sporangium dividing, but not always simultaneously, into nearly equal portions. The cell-plates then partially or entirely deliquesce into a hyaline mass, finally disappearing altogether. At the same time the structure of the protoplasm contained in the sporangium changes; it becomes more uniformly granular and transparent, a large number of small round vacuoles appearing at the same time. These partially disappear, and fresh cell-plates are again formed. Each of the portions of protoplasm separated by them contains one of the small vacuoles, and is the protoplasm of the subsequent spores. The cell-plates either form the cellulose-membranes of the spores or pass over into intercellular substance.

In *Aphanomyces* there are, however, no cell-plates; and the mode of formation of the intercellular substance presents a difficulty. It may be produced in the way described by Strasburger in the case of some swarm-spores, or it may be regarded, with de Bary, as a secretion from the mature spores.

An analogous production of temporary cell-plates has been

---

[*] Pringsheim's Jahrb. f. wiss. Bot., xiii. (1882) pp. 253–85 (1 pl.).

observed by Strasburger in the formation of the pollen of some phanerogams and of the spores of some vascular cryptogams, and in the formation of the endosperm in the embryo-sac.

The mode of formation of the zoospores of *Phytophthora* agrees with that already described in the Saprolegnieæ. In *Pythium* the formation of cell-plates is in most cases very doubtful.

The question of the presence or absence of the cell-nucleus in the sporangia presents many difficulties. In some cases round or lenticular bodies exhibiting the reaction of nuclein can be made out with certainty. In *Leptomitus* it is especially distinct, each spore possessing one nucleus. In other cases each spore contained two nuclei; while in others the presence of a nucleus could not be certainly demonstrated.

The processes which take place in the formation of the zoospores within the sporangia of the Phycomycetes must be regarded as falling within Strasburger's definition of true cell-division.

Alternation of Generations in the Hypodermiæ.[*]—M. Cornu has been able to produce the aecidium of *Puccinia arundinacea* on *Ranunculus repens* from spores, but not abundantly, and always late in the year, viz. in October and November. This species does not attack *R. bulbosus*, *acer*, *sceleratus*, or *Flammula*, or *Lonicera*. *Ranunculus acer*, *bulbosus*, and *repens* are, however, also subject to the attacks of an aecidium derived from *Uromyces graminum* Cooke; the ranunculaceous plants *Aquilegia vulgaris*, *Actæa spicata*, *Aconitum Napellus*, and *Hepatica triloba* support aecidia which are considered to be distinct from the above. The puccinia-form of *P. arundinacea* occurs on *Arundo Phragmites*; thus the species inhabits plants of very different characters at different stages of its life-history.

"Mal Nero" of the Vine.[†]—O. Comes has determined that this widespread disease is caused by a production of gum like that to which stone-fruit trees are liable, the result of insufficient nutrition; and that the fungi which always accompany it are a secondary phenomenon only. The best cure is copious manuring, and especially the abundant supply of phosphates and lime-salts.

Aubernage: a Disease of the Vine.[‡]—For some time past a disease of the vine called "Aubernage" has shown itself at Auxerre in the department of Yonne, with most disastrous results. After first small and then large spots have appeared on the branches, a rapid disorganization of the tissue of the wood commences, which, beginning at the extremities of the branches, spreads downwards to the roots and completely destroys the plant. C. Roumeguère has proved the existence of three fungi in the diseased branches. *Phoma vitis* Bk. & B., *Phoma pleurospora* Sacc. var. *forma vitigena*, and *Sphaerella pampini* Thm., and believes that in the joint action of these fungi he has discovered the true cause of the disease.

Parasites of the Saprolegnieæ.*—A. Fischer has made a detailed examination of the group of minute fungi parasitic on the Saprolegnieæ, which were at one time taken for the reproductive organs of their hosts, the organisms themselves for antheridia, their zoospores for spermatozoids. They comprise the three genera *Olpidiopsis* Cornu, parasitic on *Saprolegnia ferax*, *Rozella* on *S. dioica*, and *Woronina* on *Achlya dioica*. The mode of observing them adopted was to cultivate the *Saprolegnia*, &c., on larvæ of ephemerides, which became completely covered with the fungus in twenty-four hours, the parasite always attacking the latter after the course of a few days.

After a general description, applying to the whole group, of the structure and movement of the zoospores, and the mode in which the parasite penetrates the host, in extension of previous observations on the same points,† the author proceeds to a separate description of each genus.

Olpidiopsis is distinguished by its nearly spherical or shortly elliptical sporangia with smooth surface, which are found in swollen and deformed *Saprolegnia*-sacs. In addition to the ordinary zoospores, there occur also spined sporangia of the same size as the smooth sporangia, which perform the function of resting spores in the cycle of development of *Olpidiopsis*. The smooth spineless sporangia are developed both from the spores of the spineless and from those of the spined sporangia under favourable circumstances, a single sporangium only springing from each spore. The view of Cornu and others, that the spined sporangia are organs of a sexual nature, rests on inaccurate observation. The number of species of *Olpidiopsis* is probably much larger than has yet been described, the parasites of *Cosmarium* and other desmids probably belonging to this genus.

Rozella forms a number of closely packed sporangia in uninjured *Saprolegnia*-filaments. The wall of its sporangium is inseparable from that of its host. Like the last genus, it forms also spined sporangia. Each spore which penetrates the host developes within it a large number of sporangia, the spore appearing to lose its individuality, and its protoplasm to become intimately mingled with that of the host. The same is the case with the spores from the spined resting sporangia. This applies to the section of the genus described by Cornu, and which may be termed the *septigena*-group ; in another section the spore-forming organs are solitary.

Woronina is characterized by the formation of a sorus. The filament is divided by septa, and in each chamber is developed a sorus consisting of a larger or smaller number of sporangia. Each spore of the sporangial sorus gives birth again to a sorus, one generally springing from each spore. The author was not able to confirm the statement of Cornu that this genus produces also resting spined sporangia ; the resting condition appeared, on the other hand, to consist of the accumulation into cysts of a large number of sori, forming what may be termed " cystosores," bodies resembling in external appearance

* Pringsheim's Jahrb. f. wiss. Bot., xiii. (1882) pp. 286–371 (3 pls.).
† See this Journal, i. (1881) p. 87.

the cystoliths of Urticaceæ. Only a single species has as yet been observed, parasitic exclusively on *Saprolegnia*.

In all stages of development of all three genera cell-nuclei have been observed. Each zoospore, on escaping, contains a nucleus. No sexual reproduction takes place in any of them.

Fischer gives the following as the distinguishing characters of the three genera :—

1. *Olpidiopsis*. The single spore developes as an individual directly into a sporangium.

2. *Woronina*. The single spore becomes enclosed as an individual in a soral chamber; it then loses its individuality, and transforms the entire contents of the chamber into a soral plasmodium. From each spore is developed a single sorus.

3. *Rozella*. The separate spores lose their individuality immediately after penetrating the host, and mingle their protoplasm with that of the host. In each division of the filament there is not therefore a plasmodium sprung from an entire spore, but only a part of one; the plasmodium resulting from a spore fills the entire filament. From each spore proceeds a row of sporangia.

Olpidiopsis is the simplest form of the group, *Rozella* occupying the highest position, and the three genera are genetically connected as different stages of development. The life-history may be divided into two periods; in the vegetative period it is a naked mass of protoplasm, spontaneously changing its form, a plasmodium; the reproductive period is characterized by the separation of zoospore-producing organs.

The author considers that these three genera must form a group by themselves distinct from the Chytridiaceæ, which are characterized by a more or less developed mycelium and by a process of sexual reproduction.

Diastatic Ferment of Bacteria.[*]—J. Wortmann considers that the reason why bacteria do not, in the ordinary way, attack starch-grains, is that the starch is usually accompanied by albuminoid and other substances, from which the bacteria obtain their food-materials more readily. In order to determine the power of bacteria to decompose starch, this substance must be presented to them in a state of purity. Experiments in this direction yielded the following results :—

1. Bacteria have the power of producing in starch-grains, starch-paste, and dissolved starch the same changes as are caused by diastase.

2. Different kinds of starch are dissolved with different degrees of rapidity by bacteria, as by diastase.

3. The bacteria exercise this influence on starch only when no other serviceable carbon-compound is available, and when the access of air is not in any way impeded. Thus if only the slightest trace of tartaric acid is present in the fluid, the starch is not attacked; but when this disappears, the starch at once begins to dissolve.

4. The action of bacteria on starch is brought about by a ferment

[*] Zeitschr. für physiol. Chimie, vi. p. 287. See Naturforscher, xv. (1882) p. 321.

which they excrete for this purpose, and which, like diastase, is soluble in water and precipitated by alkalies.

5. This ferment acts only diastatically, and does not peptonize; i. e. it transforms starch into a sugar which reduces copper-oxide.

6. The ferment itself can act on starch even in the absence of oxygen.

7. The ferment is excreted by the bacteria even in neutral solutions containing starch; and under these conditions without action.

8. The action of the ferment is accelerated in slightly acid solutions.

From these results Wortmann deduces the theory that bacteria produce a ferment which peptonizes albumen, but which has only a diastatic action on starch in the absence of albumen and other sources of carbon.

Bacteria of Intermittent Fever.[*]—A. Rózsahegyi confirms the observations of Klebs and Tommasi-Crudeli[†] with regard to the efficiency of filamentous bacteria in acting as carriers of the contagion of malarial fever. Placing a small quantity of the marshy soil of a malarial district of Hungary in a drop of solution of isinglass, he allowed this to stand in a warm place, when the malarial bacilli shortly made their appearance. When mixed with pure isinglass, the culture invariably succeeded at once; but if from one of these cultures a drop is taken containing abundance of bacilli and spores, and again placed in pure isinglass, this secondary culture succeeded only in about one-third of the cases. This is attributed by Rózsahegyi to the fact that, in addition to organic matters, the bacillus requires mineral constituents for its nutrition. For the secondary culture, heating to 50°–100° C. reduced the germinating power of the bacillus by about 2 per cent.; while a temperature between zero and 20·6° raised it by 50 per cent. Moist heat hence diminishes the germinating power, while moist cold increases it. The resting spores were killed only by an exposure for two hours to a temperature of 190°–195°.

Bacterial Parasite of the Chinch Bug.[‡]—In the course of some experiments upon the chinch bug, S. A. Forbes was annoyed by their rapid disappearance, and, crushing some, examined their fluids under the Microscope. In every case these were found to be swarming with a species of *Bacterium* not easily distinguishable from *B. termo.* The observations were many times repeated with every precaution against accidental infection, but with the same results.

Careful search in the juices of the corn upon which the insects were feeding, failed to discover anything of the kind there, and if a bug were thoroughly washed in a drop of distilled water no bacteria occurred in the water, showing that they were not derived from the surface of the insect. When a number were kept for a week in a

‡ Amer. Natural., xvi. (1882) pp. 824-5.

bottle without food, the bacteria were found to have greatly increased in numbers, and were especially abundant in those which were recently dead. Dissections were made for the purpose of ascertaining whether the seeming parasites could be traced to the alimentary canal and in five cases the digestive organs were isolated and crushed. In all these cases the bacteria were very abundant, and could be seen issuing from the stomach in adherent masses, and also in motion separately in all parts of the field. In two cases where a comparison could be made between the contents of the anterior and posterior parts of the canal, they were found much the most numerous in that part of the canal posterior to the Malpighian tubes. The author therefore concludes that they have their principal, perhaps exclusive, seat in the alimentary canal.

Similar experiments made upon chinch bugs taken from the field, gave similar results throughout; but nothing of the sort could be detected in the fluids of the corn-plant louse (*Aphis maidis*) feeding upon the same stalks, nor in any of a number of insects examined.

Etiology of Distemper.[*]—Dr. R. Koch has collected together the literature which records the experiments that have been hitherto made respecting the cause of the distemper (*Milzbrand*) of cattle, and attempts to settle various disputed points connected with it.

Koch considers that a frequent source of error in the recorded results is the existence of other infectious complaints, as for example, septicæmia, which present a strong similarity to the distemper, and which are caused by similar bacilli. No certain method of distinguishing these various bacilli has yet been indicated. In opposition to the view of Pasteur that the disease always results from injury to the digestive organs, Koch maintains that infection may be carried from the intestines to other parts of the body when in a normal condition. Buchner's statement [†] that the bacilli of hay and of distemper can be mutually transformed one into the other, he also regards as resting on insufficient evidence, the requisite care not having been taken to exclude the possibility of the entrance of foreign bacteria into the culture. His own experiments showed that the distemper-bacilli could go through a very large number of generations unchanged, and still retain as great virulence as if they had been just removed from infected blood.

The author regards Pasteur's assertion, that " the etiology of distemper has been discovered, and with it the prophylaxis of this disease " as premature, many questions regarding it being still undecided. In conclusion, he discusses the question whether the bacilli of this disease can go through their course of development independently of the animal organism. He considers the evidence to be in favour of the conclusion that distemper makes its appearance in localities where dead bodies affected with it have never been buried, and where there is no reason to suppose that infected animals can

---

[†] See this Journal, *ante*, pp. 89, 382.

have brought it. He considers that it can be clearly established that these bacilli can produce spores and go through all stages of development without coming into contact with any animal substance; propagating themselves extensively on vegetable substrata in moist situations during the warm months; the spores retaining their power of vitality through the winter.

Experimental Production of the Bacteria of Distemper.[*]—H. Buchner has experimented on the methods by which the infectious fungus of distemper can be artifically transformed into the harmless hay-bacterium. Of the latter he considers the correct name to be *Bacterium subtile*. The transformation is effected by means of a contrivance which is described in detail, by subjecting the infectious fungus to the influence of abundant supply of food-material and abundant oxygen. From the true distemper-bacteria, with clear nutrient fluid and delicate white clouds at the bottom, three transition-stages are thus obtained, viz.—

1. Nutrient fluid clear or clouded with flecks; a white rim formed where the surface of the fluid touches the glass; white flecks at the bottom of the fluid.

2. Fluid clouded with flecks; very loose pellicle with a mucilaginous appearance, which sinks to the bottom with the least shaking; bottom covered with flecks and fragments of the pellicle.

3. Fluid clear or clouded with flecks; pellicle consistent, but with a mucilaginous appearance; no flecks at the bottom.

These lead to the true hay-bacteria; when these only are present, the nutrient fluid is completely clear, and there is a dry, firm, white pellicle often finely wrinkled, with a pulverulent appearance, and easily submerged.

Germs of Malaria.[†]—In continuation of the researches of Tommasi-Crudeli and Klebs,[‡] A. Ceci has further investigated the conditions under which malarial germs germinate in the soil. He concludes that in the atmospheric air and in the soil there are usually only germs or spores, which can develope under certain favourable conditions into more highly organized forms. This development almost invariably causes, in the fluids and moist substances in which it takes place, certain chemical changes, which are collectively known as fermentation. When the development takes place in nitrogenous or albuminoid substances, the highest kind of fermentation or putrefaction ensues. The effect of heat upon the germs is to retard their development, and consequently the fermentation or putrefaction. The fermentation produced by the germs in animal organisms, or fever, is retarded by the same agencies. The development of the germs may take place without causing fermentation, and is then apparently harmless.

The succession of generations of the organisms which occurs

* SB. K. Bayer. Akad. Wiss. München, 1882, pp. 147-69. See Bot. Centralbl., xi. (1882) p. 239. Cf. this Journal, *ante*, p. 89.

† Arch. f. experim. Path. u. Pharmak., xv. p. 153, and xvi. p. 1. See Naturorscher, xv. (1882) p. 332.

‡ See this Journal, i. (1881) p. 287.

under artificial conditions hinders the putrefaction which the lower organisms occasion in nitrogenous fluids, and may even entirely stop it. This appears to the author to account for the gradual subsidence and ultimate complete disappearance of fevers and other ferment diseases caused by them. In malaria, these organisms appear to lose their infectious properties very rapidly, and thus become incapable of conveying the malady from one infected animal nidus to another. Under favourable conditions they may however return to the condition of natural germs, and become once more infectious. In this way malaria may be conveyed by human subjects from an infected district to one previously free. The rapidity with which this reversion of the germs to their natural condition takes place may be the cause of the extreme contagiousness of such diseases as the distemper of cattle.

Prevention of Fermentation by Vegetable Acids.[*]—M. Märcken gives the following as the proportions of various acids which prevent a solution of sugar from fermenting:—acetic acid $0 \cdot 5$ per cent.; formic acid $0 \cdot 2$, propionic acid $0 \cdot 1$, butyric acid $0 \cdot 05$ (or completely when $0 \cdot 1$ per cent. is present), and a mere trace of capronic acid. A proportion of $0 \cdot 6$ per cent. of acetic or $0 \cdot 05$ per cent. of butyric acid in a nutrient fluid prevents the increase of yeast; while as much as $3 \cdot 5$ per cent. of lactic acid is required for the same purpose.

Fermentation of Maize-starch.[†]—V. Marcano has investigated the process of fermentation in "chicha," an alcoholic liquid prepared by the American Indians from maize-grains. He states the fermentation to be due to the reproduction of a very characteristic organism, which has three forms of development, as a vibrio, as nucleated torula-like globules, and as myceloid tubes, from which, at a certain period, vibrios escape, the membrane which forms the septa of the filament being at the same time resorbed. It is found in the exterior pellicle of maize-grains, and can be transformed from one form into another by culture in different nutrient fluids.

The ferment of chicha is further characterized by the property of acting directly on young starch, such as that contained in the embryo of maize-grains; the products of decomposition being dextrin, alcohol, and carbonic acid gas. The starch-grains on which it has acted are reduced to the condition of flakes of cellulose-starch (farinose), all the granulose having disappeared.

The organism resists the action of boiling water at 95° C. continued for some minutes; the most favourable temperature for its production being 40°–45°. It can also ferment milk-sugar, saccharose, and glucose. During the germination of maize, the vibrios develope in the interior of the grain in vast numbers. They have also been detected in the stem, immediately beneath the bark, and in the leaves.

The facts here recorded are considered by the author to explain the

[†] Comptes Rendus, xcv. (1882) pp. 345–7.

phenomenon of the resorption of starch-grains ; and of the rise of temperature which takes place during germination ; as also the production of other substances, hitherto unexplained, in the elaborated sap.

Fermentation of Nitrates.*—The researches of MM. Schloesing and Muntz have proved that nitrification, in the ground and in organic liquids, is due to development of small organisms (*corpuscules brillants* of Pasteur).† MM. Gayon and Dupetit having been led to think that the opposite process, viz. reduction of nitrates, is also a physiological phenomenon, have investigated the matter experimentally, and found a microbe which attacks nitrates in presence of organic matters (e. g. sewage water containing a little nitrate of potash with some altered urine, or preferably, chicken-broth) which cause the products of fermentation of the nitrate to enter into new combinations. Pure nitrogen is liberated, representing a large proportion of that of the nitrate, the rest forming ammonia, and perhaps amidized derivatives of the organic matter, the liquid being filled with the microbes. Carbolic acid and salicylic acid, in antiseptic, or even larger doses, not only do not hinder the life of the reducing microbe, but themselves disappear completely with the nitrate, in the same way as sugar or propylic alcohol.

Algæ.

Composition of Fucus amylaceus.‡—The chemical analysis of the alga *Sphærococcus lichenoides* Ag., known as *Fucus amylaceus*, has yielded the seven following carbo-hydrates :—

1. *A mucilage soluble in water.* The drug extracted with cold water yields a small quantity of mucilage which is precipitated in alcohol, and is converted into sugar by acids. Mannite and grape-sugar are wanting in the aqueous solution.

2. *A gelatinous non-nitrogenous substance*, with ash amounting to $4 \cdot 43$ per cent.; the analysis yielding C $45 \cdot 55$, H $5 \cdot 99$ per cent., nearly corresponding to the formula 4 $(C_6H_{10}O_5 - H_2O)$. Seven parts in bulk of alcohol produce a precipitate in the hot solution ; its solubility in cupric oxide distinguishes it from the lichenin extracted by Berg from *Cetraria islandica ;* iodine and H_2SO_4 do not colour it blue ; hence it is not a soluble modification of cellulose. This gelatinous substance must not be confounded with the pararabin discovered by Porumbaru in the Japanese Agar Agar. The aqueous solution of the foregoing turns the plane of polarization to the left, and is extremely opalescent.

3. *Starch-flour.*

4. *A pararabin-like substance.* The residue of the *Fucus* was macerated in one per cent. muriatic acid, pressed out, filtered, and the product precipitated with alcohol. The purified precipitate is a white powder containing sulphate of lime. The substance freed from ashes shows the following composition : C $44 \cdot 78$, H $5 \cdot 95$

per cent., which nearly corresponds to the formula $C_6H_{10}O_5$, and therefore closely resembles Reichardt's *pararabin*, but differs in this, that when boiled with a diluted inorganic acid it yields sugar.

5. *Metarabin.* After a second extraction with dilute hydrochloric acid, the alga being saturated with dilute caustic soda, the filtered solution precipitated with alcohol, and the precipitate purified, its reaction indicates metarabin.

6. *Wood-gum.* Obtained from the residue by the addition of 10 per cent. potash ley. Besides these was also obtained :—

7. *Cellulose.*

All these substances boiled in dilute inorganic acids pass into sugar.

Mazæa, a new genus of Cryptophyceæ.[*]—A fresh-water alga recently discovered in Brazil, belonging to the group of the Stigonemeæ, has been described by Drs. E. Bornet and A. Grunow, under the name of *Mazæa rivularioides*. This alga, remarkable in various ways, externally resembles *Rivularia plicata* Harv.; its fronds are rounded, more or less irregularly knobby, and attain to a diameter of about 25 mm.; at first solid and somewhat firm, they later become hollow and soft. The colour of moistened specimens is of a sombre green, inclining to olive. The trichomes, immersed in a homogeneous colourless jelly, spread themselves around a central space; they increase towards the periphery, and become lost in the interior. These trichomes give origin to branches, either scattered or unilateral, which elevate themselves to the same height, and to heterocysts either sessile on the side of the cells or borne on a pedicel of one to three cells; intercalary heterocysts were not observed. The heterocysts are oblong in form, easily to be distinguished from the ordinary cells by their size, and above all, by the nature of their contents, which is more homogeneous; when old, they assume a yellowish tint; the chloriodide of zinc colours them purple. When a cell forms a heterocyst or a branch, it first produces a lateral enlargement, which is very early separated. This new cell may at once change into a heterocyst, and then it will be directly applied to the side of the cell, as are the heterocysts of *Capsosira* and those on the large branches of *Stigonema*, or it may be divided once or twice before the formation of the heterocyst, which will be then pedicellated, or it may even form a cell from which a branch may arise. The branches, like the heterocysts, are not uniformly arranged along the length of the filament. At certain spots they are closer and level. Some remain simple, others ramify, none terminate in a hair. No distinct trace of a sheath was observed around any of the younger portions of the trichomes, but at the base the cells are sometimes surrounded with a somewhat thick envelope. None of the specimens (not very numerous) examined showed the least trace of spores or homogonia.

Two characters of this genus are particularly interesting, its rivulariaceous appearance, and its pedicellated heterocysts. This

[*] Bull. Soc. Bot. France, xxviii. (1881) pp. 287-8 (1 pl.).

latter peculiarity, which hitherto has not been met with among the Cryptophyceæ, indicates in *Mazœa* a degree of specialization of the parts of the trichome greater than that in any other genus of Stigonemaceæ, in fact it represents the highest development in the group. Now that in this genus and in *Capsosira Brebissonii* (= *Stigonema zonotrichioides* Nordst.), Stigonemaceæ have rivularioid representatives, it may be noted that Scytonemaceæ is the only tribe in which this type is wanting.

Resting-spores of Conferva.*—Resting-spores have already been observed by a large number of inquirers in various Confervaceæ; first of all in a *Conferva* first discovered and figured by Itzigsohn, and described by him as *Psichohormium uliginosum*; and again, by Pringsheim, Famintzin, Cornu, and Rosenvinge, in the genera *Ulothrix* and *Conferva*; and they are now found to be present in the whole genus *Conferva* (L.) Wille. N. Wille now adds to these contributions his observations on the manner of forming these resting-spores.

In *Conferva Wittrockii* n. sp. the spore-formation is thus carried on. The chlorophyllaceous contents contract and become rounded. The colouring matter collects principally in the ends of the cells, so that the substance in the middle appears nearly colourless; but after the contraction of the cell-contents the chlorophyllaceous portions of the protoplasm draw nearer together, until at last they coalesce and form a round or elliptical body within the mother-cell; they then begin to surround themselves with a membrane, which later consists of two distinct layers. The spores are generally set free by the filaments resolving themselves into H-shaped cells (in which the cell-wall of each cell has a transverse fissure in the middle of the transverse walls); the spores then fall out. Sometimes they escape by the cell-walls becoming converted into mucilage, their layers becoming gradually indistinguishable. On first germinating, the size of the spores increases, as the result of which the outer membrane bursts. The outer membrane consists of two pieces with pointed ends, one being much larger than the other, and covering it like the lid of a box. Afterwards, through the expansion of the inner membrane, the smaller piece of the outer membrane gives way, and the inner membrane grows through the aperture thus formed in the form of a tube. The development was not followed further, but the writer considers it probable that zoospores are first formed from the resting-spores.

The development in *Conferva stagnorum* Ktz. is of precisely the same character; but here the spores are mostly freed through the conversion into mucilage of the cell-walls. The germination proceeds either as in *C. Wittrockii*, or transverse walls appear in the elongated resting-spores whose outer membrane is not burst, and the young filaments are thus formed. In germination, a sort of organ of attachment is formed by an excretion of mucilage in the pointed end of the spore; or perhaps the mucilage is a local transformation of the outer membrane. In one case the author observed this sort of cell-

---

* Ofversigt af Kongl. Vetensk.-Akad. Förhandl., xxxviii. (1881), 26 pp. (2 pls.). See Bot. Centralbl., xi. (1882) p. 113.

division in various directions, and considers this phenomenon as the commencement of a palmella-condition.

A third and new species, described as *C. pachyderma*, showed a special peculiarity of the vegetative cells. As a rule the author found imbedded in the transverse walls on each side of the cells, one, and sometimes two, crescent-like particles of cellulose sharply pointed on both sides, which were distinguished from the transverse walls by their more highly refringent power. When the cells are about to transform themselves into resting-spores, they increase somewhat in size, the chlorophyll augments and distributes itself uniformly, but no new membrane appears. It seems as if one, or, perhaps more strictly speaking, two new pointed box-like interlocked layers are formed in the inner, less watery, layer of the mother-cell-wall. The wall of the resting-spore is therefore the thickened wall of the mother-cell. The resting-spores escape through the conversion into mucilage of the outer part of the cell-wall. In germination a hood-shaped piece of the outer membrane of the resting-spore remains, which is attached to the basal cell.

In *Conferva bombycina* Ag. var. *minor*, either single cells swell up into a barrel-shape, or here and there the contiguous ends of two neighbouring cells assume a club-like form. It is here that the largest part of the chlorophyllaceous protoplasm accumulates, and after this the swollen end is separated by a transverse wall from the longer narrow part of the mother-cell. The wall of the swollen part thickens later. The author considers these cells to be resting-spores, although he was not able to observe their germination. *C. bombycina* Ag. var. *genuina* has similar resting-spores.

We find accordingly that three modes of formation of the resting-spores of Confervaceæ have been observed, viz. (1) by rejuvenescence, and the formation of a new membrane round the contracting contents; (2) by the thickening of the membrane of the mother-cell; (3) by separation of a portion of the cell-substance to a swollen part of the mother-cell, and the thickening of the membrane of this portion.

Diatoms of the Baltic.[*]—H. Juhlin-Dannfelt has critically examined the diatoms of the Baltic, describing over 300 species, including a number of new species and varieties. He finds them to belong entirely to brackish forms, except where fresh water has mixed with the salt, where many true fresh-water species occur. Comparing them with the forms found in the quaternary diatom-beds of Sweden, he finds no identical species, from which he infers a diminution in the amount of salt in the Baltic in historic times.

Motion of Diatoms.—Colonel R. O'Hara writes: " As the subject of the movement of diatoms has been recently brought forward again, the following notes on the subject may be of interest :—

In washing away the acid from diatomaceous material, I have

---

[*] Bihang til R. Svenska Vet. Akad. Handlingar, vi. (1882) 52 pp. (4 pls.). See Bot. Centralbl., xi. (1882) p. 153.

constantly observed what appeared to be gelatinous casts of diatoms. In order not to lose these, I have been content to select diatoms from what would be called dirty strewed mixed slides.

In the beginning of 1878, when watching diatoms in their living state, I observed what I thought was a *Cocconeis* moving freely, and there appeared to be an undulating movement along the edge all round. On trying to isolate it I lost it under the cover.

FIG. 147.

In December 1878 I came across what appeared to be a cast of a diatom (*Stauroneis pulchella*), of which I send two photographs * by direct and oblique light. The latter is for the purpose of showing the plasticity of the material more distinctly. It is represented by Fig. 147. The striæ on three-fourths of the figure may be seen to be perfectly distinct and separate along the median line; they then generally coalesce or intertwine, separating again on nearing the edge of the membrane. In the remaining quarter the striæ have apparently coalesced completely, and have formed with the membrane a continuous surface to the point, and beyond. If this be a cast, it strongly suggests movement by cilia or undulating membrane.

It may be said that this is simply an imperfectly siliceous frustule. It must be remembered, however, that the diatom in question had to go through the usual operations of washing, &c. Also why is only one-fourth acted upon up to the median line, whereas in the other three-fourths the finest hair-like (or feather-like) portions are seen distinct at or near the median line, but converging and intertwining towards the delicate membranous looking edge?

I have also sent two photographs of a *Pinnularia* and cast, by direct light, the one showing what I take to be the siliceous frustule, well defined; the other the so-called cast, well defined,

* The photographs are deposited in the Library.

the focus being altered slightly to take the latter. (In the figure the outer edge of the cast is too hard and defined.) They are represented by Fig. 148. The differences between siliceous frustule and cast are:—In the former, every portion is sharply and hardly defined. There is no appearance of beading; altering the focus

FIG. 148.
FIG. 149.
brings out shading, and different planes of definition, showing convexity and different curves. In the latter, the median line is very irregular and interrupted, though clearly defined. The striæ are thicker, not hard edged, and show signs of beading. In many places they coalesce. The whole is well defined at the one focus, proving it to be comparatively in one plane.

In the beginning of this year, when examining for selection a mixed strewed (dirty) slide from a gathering, I found a *Navicula* (*Didyma?*), of which I have sent three photographs. It is represented in Fig. 149. Round it there appears to be a double gelatinous membrane, with radial arms extending from the siliceous frustule to the margin of the membrane, where they appear thickened. At A the arms of the lower membrane seem to show through the upper membrane, and form V's with the arms of the latter. They are finer than those arms which appear single, but which I conclude are formed by the arms of one membrane covering those of the other. At B both membranes appear, the edges forming loops. At C the membrane and arms are much extended, the arms

forming the V's being very fine. (D is dirt matter on the slide concealing portions of the membrane.)

From the above and other observations I would suggest that the movement of some diatoms is carried out by means of an undulating and extensible membrane with radiating arms. It would account well for movements as yet unexplainable, as for instance, when a diatom is fixed by one extremity, and has the other end pushed aside by another diatom. When the force so exerted is suddenly removed, the first diatom springs back into the first position, like a bent spring released, as if acting by muscular power.

Having cracked the cover-glass, I am unable now to use an immersion lens, but what I have mentioned is still visible with a good dry $\frac{1}{12}$."

Mr. H. Mills has also detected * in *Stephanodiscus Niagaræ* fine threads twice the diameter of the frustule, as Professor H. L. Smith had previously done in the same object.

Symbiosis of Animals and Algæ.†—In pursuance of his investigations on the symbiosis of certain algæ with the lower animals, G. Entz states that he has been able to detect in the pseudo-chlorophyll-bodies of the infusoria two clear spots which must be regarded as contractile vacuoles. The view previously brought forward that their presence in animal organisms is due to their being taken in with their food is confirmed by the fact that they are scarcely ever found except in the mature individual. Almost the only exception to this is the case of *Hydra viridis*, where they occur in the ova.

With regard to the designation of these organisms as parasites, the term can only be applied to them in a very wide sense, since they can live if removed from their host, which is not the case with true parasites.

Vampyrella and its Allies.‡—J. Klein has continued his observations on the interesting genus *Vampyrella*,§ and furnishes many further details respecting the development of the different species. In *V. variabilis*, he observed that the zoospores sometimes conjugate into a plasmodium even before their escape from the cyst. If the zoospores fail to conjugate, after a considerable time they will put out one or two long slender pseudopodia instead of the much larger number of shorter ones, and by this means effect conjugation with other zoospores.

V. vorax is parasitic upon diatoms, as for example *Synedra;* and in this species the conjugation of the zoospores may be very well observed. They consume the greater part of the contents of the diatom-shell. *V. pendula* occurs on several species of *Œdogonium,* and exhibits essentially the same phenomena as the preceding species. *V. inermis* resembles *pendula* in being parasitic on *Œdogonium,* and

* Amer. Mon. Micr. Journ., iii. (1882) pp. 8–9.
† Biol. Centralbl., ii. (1882) pp. 451–64. Cf. this Journal, *ante*, pp. 241, 542.
‡ Bot. Centralbl., xi. (1882) pp. 187–215, 247–64 (4 pls.).
§ See this Journal, *ante*, p. 544.

in each cyst producing only a single zoospore. It differs in the original cyst-membrane having no spines.

Associated with *Vampyrella*, the author found an allied organism, to which, from its resemblance to *Monas amyli*, he gives the name *Monadopsis vampyrelloides*. It consists of cysts from which zoospores escape in a manner very similar to *Vampyrella*, and Klein believes that it is a transitional stage of development intermediate between this genus and *Monas*.

Respecting the systematic position of *Vampyrella*, the author regards the genus as being most nearly allied to the Myxomycetes, but consisting of forms living in water. The species differ from both the Myxomycetes and the Chytridiaceæ in the absence of a cell-nucleus. They are organisms which are ordinarily propagated non-sexually by means of zoospores; the occasional conjugation of these indicating the commencement of a higher stage. An interesting difference from rhizopods, with which Cienkowski associates them, is that, unlike these low animal forms, they can only derive their nourishment from particular species of algæ. They must, however, be regarded as presenting transitional forms between the animal and vegetable kingdoms.

Special resemblances are pointed out to *Monas amyli* parasitic on *Nitella*, and to *Protomyxa* and *Myxastrum* which inhabit sea-water— all of which produce conjugating zoospores. Klein regards them as intermediate forms between *Vampyrella* and the true Myxomycetes; while *Nuclearia* and *Actinophrys* are the most nearly allied forms among rhizopods.

He proposes to establish a new family of HYDROMYXACEÆ, with the following characters:—Parasitic aquatic organisms, producing cysts, from which, when mature, one or more zoospores destitute of nucleus escape directly. At once, or at a later period, these assume an actinophrys or amœboid form, two or more coalescing with one another when meeting, and producing plasmodium-like bodies. The zoospores, as well as the plasmodia which result from their coalescence, form new cysts after absorbing nutriment. Subsequently, also, resting cysts are produced; but these are not at present known in *Monadopsis* and *Protomyxa*. The family is made up of the genera *Vampyrella*, *Monadopsis*, *Monas*, and *Protomyxa*. The following are the generic characters:—

1. *Vampyrella* Cnk. The ripe cysts contain a red or orange endochrome, with dark spots; membrane usually coloured blue by iodine and sulphuric acid. The endochrome escapes in from 2–4 (rarely more) pieces, which develope into zoospores, moving either by pseudopodia or by a colourless seam; the division into zoospores takes place during the escape. In the coalescence of the zoospores, the pseudopodia first unite, and then the body; from 2–4 (rarely more) zoospores conjugating in this way. Plasmodia small, usually resembling a large zoospore, and with neither vacuoles nor anastomoses. The plasmodia and zoospores both develope into new cysts. Resting cysts are also known. Seven species.

2. *Monadopsis* Klein (only 1 species, *M. vampyrelloides*). Cysts

small; endochrome pale red; membrane delicate, coloured blue by iodine and sulphuric acid. Endochrome escapes simultaneously in two or three portions; the division taking place before the commencement of the escape. Zoospores very small, of irregular amœboid appearance, with only a few short pointed pseudopodia. In conjugating the zoospores envelope the isolated cells of the host (unicellular algæ), forming a new cyst round them, or several individuals are thus enveloped. Resting cysts unknown.

3. *Monas* Cnk. (only 1 species, *Monas amyli*, or *Protomonas* Haeck.). Cysts spherical, with simple thin membrane and colourless endochrome, from which a number of zoospores are formed. Zoospores, at first fusiform and bi-ciliated, with serpentine motion, afterwards amœboid or actinophrys-like, with several fine pointed pseudopodia and slow movements, during which they change their form. Small plasmodia formed from the coalescence of several amœboid zoospores. The hosts (grains of starch) are surrounded by the zoospores or plasmodia, thus forming a new cyst; several zoospores often coalesce on the same starch-grain. Resting cysts formed by the ordinary cysts throwing off the unconsumed nutrient material, and enveloping themselves with a new membrane, wart-like projections appearing on the inner side of the original membrane.

4. *Protomyxa* Haeck. (only 1 species, *P. aurantiaca*). Cysts spherical, with moderately thick membrane, structureless, and not coloured blue by iodine and sulphuric acid. The fine-grained orange-red endochrome breaks up into a number of portions, each of which escapes as a zoospore. Zoospores pear-shaped, with a single cilium at the narrow end, and slow motion, subsequently amœboid and protean. Large plasmodia formed by the coalescence of several amœboid zoospores, furnished with branched anastomosing pseudopodia and vacuoles. The hosts (various diatoms) are surrounded by the amœboid zoospores or plasmodia, and their shells thrown out after their contents have been absorbed; a new cyst is thus formed, a new membrane being excreted. Resting cysts unknown.

MICROSCOPY.

a. Instruments, Accessories, &c.

Petrographical, Mineralogical, or Lithological Microscopes.—Rosenbusch, Fuess, Beck, Swift, &c.—(1) *Rosenbusch's Petrographical Microscope.—* Special Microscopes for the examination of minerals and rocks are now supplied by nearly every optician. The original of such instruments [*] is the one devised by Professor Rosenbusch, in 1876,[†] which is illustrated in Fig. 150, with a few modifications introduced in its manufacture by R. Fuess, of Berlin.[‡]

[*] A "Mineralogical Microscope" was described by S. Highley in Quart. Journ. Micr. Sci., iv. (1856) pp. 281–6 (3 figs.).
[†] Neues Jahrbuch f. Mineral., 1876, p. 504.
[‡] Cf. Loewenherz, L., 'Bericht über die Wiss. Instrumente auf der Berliner Gewerbeausstellung im Jahre 1879,' pp. 282–6 (1 fig.), pp. 350–3 (1 fig.).

Fig. 150.
The chief advantages of the instrument consist*:—(1) In the facilities for turning an object in its own plane between fixed crossed nicols, the rotation being concentric with the axis of vision; (2) In the ability to read off accurately the angle through which the object may be turned in a horizontal plane by means of the graduation round the circular stage; (3) In the facility with which the polarizer and analyzer can be displaced and replaced, and the means by which the exact position of the principal sections of the polarizer and analyzer can be noted; (4) Where the total extinction of light by means of crossed nicols interferes with the researches on any mineral, means are provided for facilitating observation under such circumstances.

The peculiarities in the construction of the Microscope consist in the tube which carries the eye-piece and objective b (Fig. 150), being as it were suspended within an outer tube p, its only attachment being at the top at l. A block k is fixed between the inner and outer tubes to prevent any rotation during focal adjustment. The coarse adjustment is effected by hand, the thumb and forefinger sliding the inner tube up and down by pressure on the disk f, other fingers being applied to the top l, of the fixed tube. The fine adjustment consists of a micrometer screw, shown at g, graduated in 500 divisions, each being equal to $1\ \mu$. The unattached portion of the inner tube is steadied in the outer one by means of a spring † and three little screws x (see side figure, a section through M—N), set horizontally and capped with scraps of parchment, which are more or less compressed as the adjustment is made. The arm of the Microscope carries two screws with milled heads, one of which is shown at n, and both at n and m in the side figure. These are set at right angles to one another, and serve to centre the tube. The eye-piece carries two cobwebs, which intersect at right angles in the centre of the field. To the outside tube of the eye-piece a small peg a is fixed, which slides into a corresponding slot in the top of the inner movable tube of the Microscope. This arrangement prevents any rotation of the eye-pieces, and so keeps the cobwebs in a fixed position. An analyzer s, fitting in a brass cap, slides over the top of the eye-piece. The bottom of the cap is surrounded by a bevelled flange, which is graduated to 5°. An index mark on the plate f, serves to record the angle through which the prism is rotated. The stage of the Microscope is circular, and a circular plate T is arranged so as to revolve horizontally on it. This plate is graduated on its margin, and an index to record the amount of the revolution is attached to the front of the fixed stage at i. It also has a spring clip q, and a Wright's indicator (two scales at right angles). Beneath the stage is set an easily displaceable polarizer r, consisting of a Nicol prism, which revolves within its external tube by means of the lower disk, which is graduated to 10°, and has its index marked on the fixed outer tube. This polarizer does not turn when the stage plate is rotated, but

---

* See Rutley's 'Study of Rocks' (8vo, London, 1879) p. 54.
† In the figure, in order to show the spring, it is brought too far round by 45°.

remains unaltered in position. A plate of quartz for circular polarization 3·75 mm. thick, and mounted in a little brass fitting, is shown at z. It slides into a slot t, situated close to the lower end of the inner microscope-tube and above the objective. The movement imparted to the microscope-tube by the screws n m, tends to throw the analyzer slightly out of position with regard to the polarizer, but Professor Rosenbusch finds that this produces scarcely any appreciable error.

For very strongly convergent light, the ordinary condensing lens (with a focus of 12 mm.) attached to the Nicol, is combined with a second one of only 8 mm. The axes to these mineral sections can thus be recognized without an eye-piece and with the objective alone.*

The stauroscopic eye-piece is shown in the side diagrams A and B of Fig. 150. The eye-lens is attached to a separate tube sliding in that holding the field-glass, and can be brought closer to the latter. The tube of the field-glass has a slit in which a pin a, inserted in the eye-lens tube, slides. The pin also passes into a slit in the micro-scope-tube, and thus fixes the position of the eye-piece. At c is a plate of calc-spar in the focus of the eye-lens. This was first used by Professor Calderon for stauroscopic measurement, and afterwards adapted to the Microscope by Fuess. For the purpose of accurately indicating to the eye the correct position with regard to the optical axis of the instrument, a cap with a very narrow diaphragm d is added, there being another diaphragm at c.

Professor Rosenbusch points out that the use of this Microscope is not confined to the purpose for which it was designed, but that it is also available for other microscopical purposes where exact measure-ments are required.†

(2) *Fuess's "large Microscope for mineralogical and petrographical observations"* (Fig. 151), is designed as an improvement upon the pre-ceding, especially as regards the stability of the centering arrange-ment. The sliding coarse adjustment is done away with, and instead of it, the stage c with the illuminating apparatus is attached to the slide d which moves on the upright support f of the stand to a distance of about 1·5 cm. (by means of the rack-work attached to d and actuated by the pinion e), and is held in the required position by the clamping screw behind. The fine adjustment is effected by the usual graduated micrometer screw. By the use of intermediate pieces of tubing the objectives can be so attached to a horizontal revolving plate a, that they all stand at about their focal distance from the object if the slide is of ordinary thickness. The centering of each objective with the optic axis of the tube b is then effected by three adjusting-screws below the revolving-plate, so that the arrangement

---

* See this Journal, i. (1878) p. 207.

† The graduation of the micrometer-screw and the addition of the plate of calc-spar and the Wright's indicator, appears to have been suggested by Professor A. v. Lasaulx. Cf. Bull. Soc. Belg. Micr., iv. (1878) p. clxxvi. The Microscope described by M. Renard, Bull. Soc. Belg. Micr., iv. (1878) ccxv., and this Journal, i. (1878) p. 270, appears to have been a Rosenbusch-Fuess instrument, but with the Lasaulx improvements and the addition of the quartz plate.

at the lower end of the tube of the Rosenbusch instrument is unnecessary. The diaphragm and polarizer can also be centered by means of the rectangular stage movements actuated by the milled

Fig. 151.
heads m and n. The former movement is made to do duty as a screw-micrometer, having a drum p attached, engraved with 125 divisions, each having the value of $0 \cdot 002$ mm., the screw pitch being $0 \cdot 25$ mm. The revolutions of the screw can be read off on an index i. The margin of the stage is graduated and also dentated, so that it can be turned by the finger. For convergent light, two Bertrand lenses of 12 and 8 mm. focal length are placed above the polarizer, and a third above the objective.*

Fig. 152.
(3) *Beck's Lithological Microscope* (Figs. 152–4).—This instrument (Fig. 152) is modelled on the plan of the " Economic " Micro-

* Cf. this Journal, i. (1878) p. 292.

3 L 2

scope with the alterations necessary to fit it for lithological examinations. The coarse adjustment is effected by the usual rack-and-pinion, and the fine by a micrometer-screw with a divided milled head, representing thousandths of an inch, for the approximate measurement of sections, &c. The stage is divided on the edge to degrees, and has a vernier reading to 10′, adapting it for use as a goniometer or for stauroscopic measurements, &c. It rotates concentrically with the optic axis, and to compensate for any slight variation in centering there is a centering nose-piece. Immediately above the latter is a Klein's quartz plate fixed on an arm by means of which it can be

Fig. 153.
Fig. 154.
turned up out of the field with great facility as shown in Fig. 153. One of the three milled heads at the end of the body-tube effects this movement. The other two milled heads are for centering the objective, and their action is shown in the same figure.

The analyzer rotates freely over the eye-piece (Fig. 153), and has an index which by a divided plate on the draw-tube allows it to be read in any position and recorded. Between the analyzer and the eye-piece is placed a plate of calc-spar cut at right angles to the optic axis for stauroscopic measurements. The eye-piece has cross cobwebs. The rotating polarizer also has a divided circle to register its position, and it is fitted into a swinging arc which is in contact with the bottom of the stage, thus excluding any false light. By means of a hinge it can be instantly turned away from the stage (in the way shown in Fig. 154) when ordinary illumination is required. A condenser of large aperture, fitting into the tube of the polarizer above the prism, is intended for the examination of the interference brushes and rings in crystals with convergent light. This also is easily removed when not required. When the instrument is used for this purpose a lens is screwed into the lower end of the draw-tube.

The instrument, though specially constructed for the study of rock sections, can be used for any other work. It is only necessary to remove the analyzer and polarizer. The fitting on the swinging arm which carries the polarizer will take any other substage apparatus such as parabola, achromatic condenser, &c.

(4) *Swift's Petrological Microscope* (Fig. 155).—The general basis of this is Mr. Swift's well-known "Challenge" stand (see Vol. I. (1881) p. 810). A special arm carrying the polarizer is added so that it can

FIG. 155.
be readily turned away when not required, and a tube inserted in
its place for sub-stage apparatus.   The fitting of the polarizer is
graduated and a spring catch indicates when the prisms are
crossed.   The rotating glass stage is graduated, and has a "self-
centering" arrangement.   Two sliding boxes at the lower end of the
body-tube serve to carry the analyzer and, below it, a Klein's quartz
plate, which can thus be readily slipped in and out.   An extra
analyzing prism with divided circle is placed over the eye-piece
(which has crossed spider-lines) with a contrivance for rotating
crystals between it and the prism.

There is also a new arrangement for showing the rings in biaxial
crystals of extreme wide angle, diopside for instance, with its entire
system of rings being (it is claimed) "exhibited as large and with
greater brilliancy than with Nörremberg's Polariscope."   For this
purpose an achromatic lens is interposed by means of a supplementary
draw-tube between the eye-piece and objective, an optical combination
of large aperture being fixed over the polarizer.

Mr. Bulloch, of Chicago, has also issued a Microscope for the
study of rock sections, adapting for the purpose the model shown in
Fig. 140 of Vol. III. (1880) p. 1077.   Cf. also Rutley's, Vol. II.
(1879) p. 470, Nachet's Petrographical Microscope, Vol. III. (1880)
p. 227, and Vérick's Goniometrical Microscope for Mineralogy,
Vol. I. (1881) p. 812.

"Jumbo" Microscope.—The instrument, from Mr. Crisp's col-
lection, shown in Fig. 156 (about $\frac{1}{5}$ nat. size) is another of the numerous
instances of misdirected ingenuity in the designing of Microscopes.
It was made in 1851 by G. Lowden, junr., a Dundee optician, for a
gentleman then lately returned from India.   It stands 4 feet high,
weighs $1\frac{1}{2}$ cwt., and the body-tube is 4 inches in diameter.   It is
therefore entitled to the distinction of being the largest and heaviest
Microscope made within modern times! *

For the coarse adjustment the stage is moved up and down along
the bar which supports the body-tube, its movement being controlled
by the large milled head on the upper end of the bar.   The fine
adjustment is worked by the milled head and rod attached to the body-
tube, by which an inner tube carrying the objective is raised or
lowered.

As the stage is so far from the observer its movements are effected
by the two longer rods terminating in milled heads shown in the
figure above the end of the bar.   One of these moves the stage from
back to front, the other turning it to either side on a pivot at its base,
giving it therefore a movement in a segment of a circle.   The re-
maining shorter rod has a screw at its lower end which, working in
a toothed wheel on the axis, causes the body of the instrument to
incline as may be desired.   The eye-piece is pierced with a slit to
admit a slide holding prepared paper for "calotyping" an object by
the old paper process.

* Schott, 'Magia Universalis,' 1677, describes and figures Microscopes of
enormous size.

Fig. 156.

THE MIDGET
THE JUMBO.

"**Midget**" **Microscope.**—Fig. 156 also shows this Microscope to the same scale as the previous one. It was made by Mr. S. Holmes, and is only $4\frac{3}{4}$ inches high with a diameter of body-tube of less than $\frac{1}{2}$ inch. It is probably the smallest working instrument ever made.

Beck's Histological Dissecting Microscope.—This instrument (Figs. 157, 158) combines a compound with a simple and dissecting Microscope, the stout arm holding the single lenses being made so that a compound body (fitted with "Society" screw) can be substituted. A speciality consists in the adjustment of the mirror, which can be used as in Fig. 158 for transparent objects, or can be brought above the stage as in Fig. 157 for opaque ones.

FIG. 157.
FIG. 158.
Gundlach's Globe Lens.*—This is a perfect sphere, consisting of a hollow flint-glass globe, made in halves, and enclosing a solid crown-glass globe. It is said to be constructed " according to a new optical principle discovered by Gundlach. By this principle the aberrations are corrected to a higher degree than has heretofore been attained by any other construction. The lens has an optical axis in any direction, hence the field is perfectly flat and distinct to the outer edges; and what is true of no other lens, the field is always the largest possible."

There are five sizes, 1, $\frac{3}{4}$, $\frac{1}{2}$, $\frac{3}{8}$, and $\frac{1}{4}$ inch.

* 'Descriptive Price List of Gundlach's New and Improved Objectives,' March 1882, p. 8.

Designation of Eye-pieces.*—At the Elmira meeting of the American Society of Microscopists, Dr. R. H. Ward, the chairman of the committee on eye-pieces (*ante*, p. 103), reported, that "all manu-facturers but one had agreed to designate their eye-pieces by their focal-lengths, but no agreement had yet been made as to the diameter of the tubes." The committee was continued for another year.

Objectives of small and large Aperture.†—The Rev. W. H. Dallinger writes on this subject as follows:—" No one has appre-ciated or found more pleasure and profit in the use of the large angles with which our lenses have been more and more perfectly provided for the last ten or twelve years than I have. As they have been produced I have obtained them each and all, that had any real value, whether produced in this country, the Continent, or America, and in some cases I have incited certain English makers to produce certain special formulæ during that time. But while I have used all lenses, from the $\frac{1}{4}$ to the $\frac{1}{50}$, constantly during this time, what work I have done could never have been accomplished if I had *only* had lenses with *large angles* to work with. Much that had been done could never have been done *without them;* but the work, as a whole, could never have been done at all if only such had been at my disposal. Hence I have, in all my special working powers, *three* lenses of the same power, and in some cases four, and *each* of them, in following out the details of a life-history of an organism, say of the $\frac{1}{3000}$ to the $\frac{1}{6000}$ of an inch in length, is absolutely needed, and its place cannot be supplied by the other. Thus, I have two $\frac{1}{50}$ths, one having a very low angle, and the other as great a numerical aperture as an oil-immer-sion can provide when worked by the best makers. In the $\frac{1}{35}$th, I have but one lens, a medium angle, because it was intended only for general work and, mainly, central illumination. I have, however, three $\frac{1}{25}$ths, four $\frac{1}{16}$ths, and so on; and I know exactly what each will do, and no more attempt to get the work of one out of the other than the maker of them would attempt to get their several results by grinding them to the same formulæ.

I talked this matter over in detail, pointing out results, six years ago with some leading experts; and although, during two or three years, many have thought that Abbe's mathematics and views were adverse to this view of mine, I felt convinced by reading between the lines of his papers, and remembering their special object, that it was not so. Still Dr. Carpenter was good enough to get a detailed view of my experience and opinion before publishing the last edition of 'The Microscope,' and he has in his preface and throughout the volume, given in effect my views, which now the unmistakable decla-rations of Abbe coincide with and confirm. The homogeneous lenses have given me splendid results, some of which will shortly be published; but *no* immersion lens of *any* kind *could* be used to work out to the end an organic life-history—that is, if it involved life and movement, because the object being in a limited area, and possibly in fluid, the fluid *under* the cover does (when the movements of

---

* Amer. Mon. Micr. Journ., iii. (1882) pp. 175 and 171.
† North. Microscopist, ii. (1882) pp. 288–9.

the object are followed) at length, without the spectator's knowledge, mingle with the fluid *above* employed for the lens, and thus destroy the whole object of search and study.   This fact, then, makes air angles of the highest importance, and I hope the highest results have not yet been attained with them.   In the main, then, I agree with Abbe."

At the Montreal Meeting of the American Association for the Advancement of Science, Dr. W. B. Carpenter gave an address on the practical and theoretical results in the history of the Microscope, in which he dwelt mainly upon the question of wide aperture and high power eye-pieces.

Correction-adjustment for Homogeneous-immersion Objectives.*

Dr. L. Dippel has already briefly published his objections to the use of a correction-collar in the case of homogeneous-immersion objectives (in opposition to the contrary opinion of Dr. H. Van Heurck) which he considers to be an abandonment of the practically most important advantage for scientific work which homogeneous-immersion has brought us, but is now led to return to the subject by the recent publication of the views of Dr. G. E. Blackham † (also of Dr. J. Edwards Smith ‡), in favour of the retention of the correction-collar, and he accordingly discusses the subject in some detail.

If we consider the matter first from the side of theory, it must on the one hand be allowed that the correction-collar, from a purely theoretical point of view, may have certain (though as will be seen in the sequel practically unimportant) advantages, while on the other hand it is undoubtedly the fact that the other advantages ascribed to it must be regarded as imaginary.

The advantages relate essentially to the following points :—First, with the correction-collar we are not so strictly limited to an immersion fluid of a particular index of refraction, as we are in the case of the fixed mounting, but various fluids can be used, which are different within certain—though always very narrow—limits.

In the use of an immersion fluid not precisely of the same refractive index as crown glass (which is the case with most of the immersion fluids hitherto employed, except the thickened cedar-wood oil), we can still obtain perfect correction for cover-glasses of varying thickness.

Further, those aberrations (comparatively considerable) can be corrected, which occur with dry preparations (rarely, however, coming under consideration in the scientific use of homogeneous immersion), if they do not adhere closely to the slide, but are separated from it by a thin stratum of air.

Finally, the correction-collar allows the same objective to be used with a longer or shorter tube, while otherwise one is confined to somewhat narrow limits in the length.

All the other advantages, however, urged by the advocates of the correction-collar are only imaginary, such as the possibility of most exact correction for the change in the index of refraction of a par-

ticular immersion fluid, in consequence of variations in temperature; or of an alteration in the optical properties of the cover-glasses, and the different powers of accommodation of the eyes of different observers.

The author has already shown [*] the practical insignificance of the difference in the refractive index of the immersion fluid produced by the varying temperature of the observing room in the ordinary use of the objectives in question, where the changes of temperature cannot be very important. Theoretically considered also, the matter will be seen to be of only little moment. According to the measurements of Professor Abbe, the difference with cedar oil is but $0 \cdot 003$ for a variation in temperature of $3°$ C. Since the correction of the objectives is arranged for a medium temperature of from $18°$ to $20°$ C., and the temperature at which normal microscopical observations are made is certainly (even if we allow very wide limits) between $15°$ and $28°$ C., the greatest deviation from the mean value in the refractive index is at most two or three units in the third decimal place. The aberrations in the divergence of the incident rays connected with this slight change and the consequent disturbance of the spherical correction, whilst it can be demonstrated by *very accurate* testing on the silver plate, is nevertheless in any case much smaller than those deviations from the *best* correction which occur with the correction-collar. It therefore follows that this much enforced deviation in the refractive index of the immersion fluid, caused by variations of temperature, which is to be balanced by the correction-collar, is at all events the *lesser* of two evils, and consequently can furnish no pretence for doing away with the fixed mounting.

Still less than the above-mentioned variations can the differences in the refractive index of different cover-glasses give any inducement for the introduction of the correction-collar. According to the observations of Professor Abbe during a period of ten years, these differences are so extremely small that they may be regarded practically as nil.

Finally, the suggested influence of the different powers of accommodation of the eye must be relegated to the region of dreams, as a simple theoretical consideration will show. If we take for example a power of 800, and two observers whose eyes are accommodated respectively to 100 mm. and an infinite distance, the difference in the adjustment thus produced—that is in the actual object-distance, assuming the objective to have air on both sides of it—can be easily computed from the formula:—

$$x \, x^* = - f^2.$$

For a long-sighted eye (where $x^* = \infty$)

$$x = 0.$$

For a distance of vision of 100 mm. (where $x^* = -100$) $x = \dfrac{f^2}{100}$, and since in the Microscope as a whole $f = \dfrac{250}{N}$,

$$\therefore \; x = \left(\frac{250}{N}\right)^2 \cdot \frac{1}{100}.$$

[*] Bot. Centralbl., No. 6.

Consequently, in the case assumed above of a power (N) of 800, x is rather more than $0 \cdot 0009$ mm. (or $0 \cdot 9\ \mu$), or if the object is in a medium of $n = 1 \cdot 50$, not quite $1 \cdot 5\ \mu$. This exceedingly slight displacement of the focus forms the measure of the alteration in the path of the rays in the objective, and it is the aberration which corresponds to the difference in the visual distance, assuming that accurate correction is first made for $x = 0$: much less if the largest possible aperture is assumed for that x, and generally not ascertainable, since it depends, like the moving of the lenses towards each other (by the correction-collar) upon the particular construction of the objective. Let us, however, assume that this movement of the lenses which is necessary for the equalization of the very slight difference in the path of the rays corresponding with the above ascertained difference of adjustment (and of the consequent disturbance of the spherical correction), amounts to even $0 \cdot 1\ \mu$, or $0 \cdot 0001$ mm., which is certainly *far too high*, this would still be a quantity which is unattainable by any *mechanical contrivance*, least of all by such a mechanism as the correction-collar. If Dr. J. Edwards Smith adduces against the results thus established by theory, a case in which three divisions on the scale of the correction-screw would be required for the equalization of the difference between the power of accommodation of his own eye and that of another observer (Mr. C. Spencer), it must be said that such a thing is entirely absurd. It proves in fact simply that what he regarded as the action of different powers of accommodation, was nothing more than an effect of "personal equation" in the judgment of the best image, and therefore rests entirely on purely subjective opinions.

If we now further examine the matter from a practical point of view, it may be at once allowed that the *technical* considerations against the correction-collar are not so weighty that it should be set aside on that account if *really practical* advantages were to be gained by it. For even if the greatest perfection of centering (such as is possible with the fixed mounting) cannot be obtained with the correction-collar nor its durability guaranteed, yet according to the examination by Professor Abbe of the correction-objectives of Powell and Lealand and Zeiss, a sufficient amount of accuracy can be obtained by very careful work. The question of expense, which the author previously laid stress on, need not be considered, because, as Professor Abbe observes, the technical difficulties in mounting the fixed objectives (on account of the final adjustment of the distances of the lenses to fractions of a hundredth part of a millimetre), are not less than in those with the correction-collar, and therefore the price for both kinds is about equal. In this respect, therefore, there is nothing to urge against the introduction of the correction-collar.

Now, however, the question arises, how and to what extent the *possible* advantages suggested by theory can be realized in practice without prejudicing the usefulness of the objectives, and on this point the author is strongly convinced that in the proper scientific use of the Microscope for the examination of *unknown objects and structural*

elements, the advantage to be expected by the use of the correction-collar is not only absolutely *illusory,* but that it is attended with many serious disadvantages.

In the observation of diatoms, which one has seen so often, and the structure of which is so simple and characteristic, it is not a matter of great difficulty to find *approximately* the best correction by experiment, since one forms a judgment from the clearness and distinctness of the image. For those, therefore, who study preferably the structure of diatoms, or who have set themselves the task of demonstrating test-objects a number of times (from whom has originated the desire for this contrivance), the correction-collar may prove of some slight advantage in the sharpness of the image, and for that reason may appear to be a desirable requisite. For this class of observation it may be readily admitted that at least no important disadvantage can arise.

For histologists, however, the case is very different. With the objects that come under their observation, especially if they are of very delicate and complicated structure, it is almost impossible to find the best correction by mere trial. In endeavouring to find the " best image " we are just as likely to arrive at a completely *false* correction (which produces *false* images) as upon the proper one. The widest latitude is thereby given to every possible subjective fancy and false arbitrary interpretation, and those deviations from the best correction which still remain, in the in other respects skilful use of objectives with fixed mounting and carefully corrected for a given length of the tube and a particular immersion fluid, are perfectly insignificant and harmless as compared with the great uncertainty and grave aberrations which the use of the correction-collar introduces.

If the best correction for a certain thickness of cover-glass is required, there is only *one* object by means of which this can be obtained with perfect certainty and with the smallest amount of subjective fancy, so that correct images of all objects of any structure can be guaranteed (without false differences in level, &c.). This object is the Abbe test-plate, by which the correct co-operation of all zones of the aperture can be judged of. That, in comparison with this plate, the structures of the valves of the Diatomaceæ are by no means sufficient, is best proved by the case brought forward by Dr. Edwards Smith, in which personal equation evidently played no unimportant part. And if even in the case of such an object—striæ of diatoms of well-known nature—such latitude was given for the exercise of personal caprice in the adjustment of the correction-screw for the " best image," how great may it be when we are dealing with *unknown* delicate and complicated structures ? Under such circumstances, how easily may the employment of the correction-collar become rather a subject of misuse than of use ? With high power dry objectives and water-immersion objectives the correction-collar is a necessary evil which must be endured. Where, however, it can be dispensed with, it would be folly to retain it on account of entirely subordinate and unimportant advantages. Especially may it be *very decidedly rejected* in all scientific work with homogeneous-immersion objectives. The slight restriction in the use of objectives with fixed mounting can the

more be endured, since on the one hand each of such objectives can be adjusted according to desire for the short Continental or for the long English tube, and thus effect can be given to personal inclinations; while on the other hand, where it is a question of *sharpest* observation, it is easy to provide a suitable medium thickness of cover-glass where the immersion fluid is not exactly uniform with crown-glass. Under all circumstances one gives up in using the fixed mounting only *unessential* conveniences and benefits hardly worth consideration, whilst far greater advantages are gained and very considerable defects avoided.

In conclusion, therefore, Dr. Dippel repeats:—" For all histological and similar scientific observations, hold firmly to the fixed mounting for homogeneous-immersion objectives.   And if we have such an objective with correction-collar, I say with Prof. Abbe, ' after careful testing of the best correction for *medium conditions* by means of the silver plate, screw it up *tightly* ("niet und nagelfest," clinched and riveted), so that no mischief can arise.' " *

Nelson's Adapter for Rapidly Changing Objectives.—This appliance has been devised by Mr. E. M. Nelson to facilitate the rapid interchange of objectives without the necessity of triple or quadruple nose-pieces, or such an alteration of the existing system

FIG. 159.

as would prevent the free interchange of objectives provided with the normal Society screw, as is the case with the devices of Parkes, Nachet, and Vérick.

In Fig. 159 N is an adapter,† the inner screw-thread of which is filed down smooth in three equal and equidistant segments, leaving the thread intact in the intervening three segments.   The screw-thread on the objective is filed down in three places to correspond with N, so that where the gauge-slots S and S′ coincide the objective can be pushed in for the length of the screw, and then an eighth of a turn to the right screws it securely " home," just as it would be after the four turns required with the Society screw and ordinary nose-piece.   Similarly to detach it, only an eighth of a turn to the left is necessary.   Whilst the objective can be inserted at any of the three positions in which the segments of the nose-piece and objective coincide, it is only in the one position where the gauge-slots S and S′ coincide, that the screw-threads correspond, and the one-eighth turn for screwing " home " can be made without injury to the threads.‡

* Cf. the discussion on this paper, Proceedings, *post*.
† By a mistake of the engraver the outer screw of N is drawn of less diameter than that of O.   They are both of Society gauge.
‡ Since the construction of the adapter, Mr. Nelson's attention has been called to a communication in 'Science-Gossip,' 1879, p. 18, in which Mr. James Vogan suggested a similar system under the heading " A Substitute for Nose-pieces."   The plan then proposed by Mr. Vogan involved cutting away two segments of one-fourth the circumference of the screw-thread.

If the thread of the nose-piece of the Microscope is filed down in the same way as in the adapter N, the latter may be dispensed with, and it is, as we have said, a special feature of Mr. Nelson's suggestion that the alteration to the objective thread in no way hinders its use with the ordinary nose-piece, and unaltered objectives will in the same way fit nose-pieces which have been filed down.

Gundlach's Calotte Diaphragm.—Mr. Gundlach has devised the very neat form of calotte diaphragm shown in Fig. 160, for application to his "College" Microscope (*ante*, p. 670).

Fig. 160.

The calotte C is pierced with five apertures, varying in size from a pin-hole to $\frac{1}{6}$ inch, and is attached to a hollow metal hemisphere H, by a screw at a point 45° from the vertex, which allows it to rotate so that the apertures pass successively over an opening O at the top of the hemisphere. H itself is fixed to a spherical segment of metal, and the latter to a short piece of cylindrical tube so as to slide into the substage R; an outer shell S, of ebonite, rotates round H, and the edge of the calotte C being milled and in close contact with S, the rotation of the latter causes the calotte to revolve also. A projecting pin on the tube fits into a slot in the substage ring to prevent H from rotating.

More space for the hand between the stage and the outer edge of the ebonite shell would be obtained by adopting a conical instead of a spherical form of shell.
Bohm's Wool-measurer.[*] — This (Fig. 161) is intended for

Fig. 161.
examining the wool of sheep under the Microscope, but it can also be used for the anthropological comparison of human hair, as well as for

[*] Bericht u. d. wiss. Instrumente a. d. Berliner Gewerbeausstellung im Jahre 1879 (Loewenherz, 1880) pp. 313–4 (1 fig.).

other fibres.   The hair or fibre is placed between two pincers a (exactly at their points). One of these is movable on the base-plate c, by means of the screw b, and the object can therefore be stretched, and the extent of the stretching read off on the scale on the plate. As, moreover, they each move on their axis, the object can be uncurled in case it is twisted, and the movement registered on a scale on the end of the screw d, to which an index is also attached.   In order to be able to measure the various diameters of the object, it is necessary sometimes to turn it entirely round. For this purpose the bar e is added, whose two milled heads f are pressed towards the corresponding ones of the pincers a by means of the screw g, so that they act like cog-wheels. The simple turning of the bar e by means of the third milled-head h sets both the pincers in equal rotation.

This instrument also provides means for chemical treatment. For this purpose the base-plate has two spring-pieces l for the reception of a small slide. These supports are raised up when the pressure of the screws m is released, so that the object may lie on the slide. A glass cover can be placed over it, and the object treated in the usual way with alkalis, acids, &c.

By sliding the apparatus upon the plate n (clamped to the stage of the Microscope), the object can be passed across the field.

Gundlach's Substage Refractor.[*]—The formula in the description of this apparatus at p. 692 was taken verbatim from the original source, and in the bibliography at p. 699 we noted a further article by Mr. Gundlach (with a different heading) as "apparently the same as the preceding." On comparing the two articles, however, it will be seen that the earlier one was somewhat hastily prepared, and that the formula should stand as in the later one as follows:—

"For the determination of the angular aperture of objectives, if not less than 96° in crown glass, I propose to attach to the front surface of the objective, by means of a 'homogeneous' medium, in the usual way, a small piece of crown glass, which has, besides the adhering surface, two other polished plane surfaces at right angles to the former and parallel to each other, with a distance between them of at least the diameter of the front lens of the objective.

Then from two distant points, lying in the plane described by the optical axis of the objective and the perpendicular upon this axis and the parallel plane surfaces of the glass piece, let rays of light fall upon these surfaces, to pass through the glass and then through the objective.

Find, in the usual manner, by moving the lights sideways, that direction of the two light rays by which the latter will just strike the outer edge of the aperture of the objective.   Then determine the angle described by the two rays before entering the glass piece, and find the true crown-glass angle of the objective by calculation after this formula:—

$$\frac{\cos i}{r} = \cos a,$$

i being half the angle of the two rays before entering the glass piece;

[*] Amer. Mon. Micr. Journ., iii. (1882) p. 176.

r, the refractive index of the glass piece; a, half the crown-glass angle of the objective."

Apparent Size of Magnified Objects.*—Prof. W. H. Brewer read a paper before the Section of Physics, at the Montreal Meeting of the American Association for the Advancement of Science, in which he gave the results of a long series of experiments on the apparent size of the image formed in the Microscope, as seen by different persons. About 440 different persons were questioned as to the size of the image of various objects, but finally a small insect was selected as the test object. The actual length of the image, as drawn by the camera lucida, using a $1\frac{1}{2}$-inch objective, was $4 \cdot 66$ inches, including the antennæ, $4 \cdot 87$; the diameter of the field was $5 \cdot 85$ inches.

The results may be briefly summed up as follows:—Of the 440 persons, about 41, or 9 per cent., judged the size quite correctly; 82 of them, or 19 per cent., made the size $4 \cdot 25$ to 5 inches, which was reasonably good. The greater number of persons underestimated the size; 2 estimated it at less than 1 inch, 7 made it over a foot, 45 made it 2 inches, or less; 22 made it 10 inches. The largest estimate was by a mechanic, who said it looked like a picture projected on a screen and it seemed to be 5 feet long. Experience seems to correct false estimates, as was illustrated by three estimates by a gentleman who used the Microscope in drawing; in three successive years his estimates were respectively 9, 8, and 7 inches.

Committee on Ruled Plates.—At the meeting of the Section of Histology and Microscopy of the American Association for the Advancement of Science, at Montreal, after the reading of a paper by Professor W. A. Rogers on ruled lines, a resolution was proposed that a committee be appointed to receive ruled plates from different makers that might be offered for examination in accordance with the suggestions made by Professor Rogers. After some discussion the resolution was carried, but it was afterwards decided to postpone the appointment of the committee until some future time.

Professor R. Hitchcock regards this † "as a great step toward the settlement of the question of the practical limit of resolution, independent of any theoretical considerations," and "hopes and believes that at the next meeting of the Association a committee will be appointed."

Quekett Microscopical Club.—It has been determined to give a series of demonstrations upon elementary subjects connected with Microscopy on the "Gossip" evenings of this Club. The first six will be on the following subjects:—Dec. 8, 1882, The History of a Stained Section of an Animal Structure, by Mr. J. W. Groves. Jan. 12, 1883, Photo-micrography, by Mr. T. Charters White. Feb. 9, Sea-side Collecting, by Mr. A. D. Michael. March 9, Some Methods of Preparing Parts of Insects for Microscopical Examination, by Mr. E. T. Newton. April 13, Microscopical Vision, by Mr.

* Amer. Mon. Micr. Journ., iii. (1882) p. 161.
† Ibid., pp. 197–8.

W. T. Suffolk.   May 11, The Structure of Mosses, by Dr. R. Braith-waite.

We are glad to find that this experiment is at last to be tried. That it should be done has been for several years the strong wish of many of the members. As, however, it was found that the suggestion gave offence to leading officials of the Club, it was not further pressed, in the hope that at some future time the force of events would enable the question to be dealt with on its merits and apart from any personal predilections one way or the other.

Hogg on the Microscope.*—A new (10th) edition of this book (bearing the date of 1883) has just been issued. It is now so well known from the numerous editions through which it has passed, extending over a period of nearly thirty years, that it is superfluous to describe its general plan. The new edition bears the marks of extensive revision, especially in the parts relating to the Microscope proper, which have in fact been nearly rewritten.

It is almost unnecessary to say that the book contains that without which no treatise on the Microscope is now complete, viz., an explanation of the Abbe theory of microscopical vision, and of the *pons asinorum* of the old school of microscopy—the aperture of objectives. Pages 69 to 80 are devoted to the most succinct and at the same time complete statement of the latter subject that has yet been printed.   A similarly succinct statement of the principles on which homogeneous-immersion is based is given in pages 82 to 86. A chapter has been added on the application of the Microscope to mineralogy and spectroscopic analysis and the examination of potable water.

By a slip the preface omits to mention that more than fifty of the new woodcuts were lent by the Council of this Society, having originally appeared in this Journal.

The author may be congratulated on the issue of the new edition and on the fact that his book has so long maintained so large an amount of popularity.

Wright's Experimental Optics.†—This is also a book on which the author may be very much congratulated, as in our view it is by far the most useful work on its subject to which the general body of microscopists can refer. It is written throughout from an experimental point of view, and the author's endeavour (to use his own words) has been " to place clearly before the mind of the reader, through something like a complete course of actual experiments, the *physical realities* which underlie the phenomena of Light and Colour.   As helps, there are solely employed simple mechanical analogies, and a few diagrams, explained in language which it is hoped may be found in reality simple and clear though not intended to be childish or to debar any private student from the healthful exercise of now and then considering what the writer means."   We think that the author's explanations

β. Collecting, Mounting and Examining Objects, &c.

**Methods of Microscopical Research in use in the Zoological
Station at Naples.***—Dr. P. Mayer gives an account of the methods
employed at the Naples Zoological Station for preserving, staining,
and mounting objects, some of which have not previously been
published. Although they are only mentioned in connection with
marine forms they are in many cases applicable also to fresh-water
organisms, insects, &c.

I. PRESERVATIVE FLUIDS.—*Killing, hardening*, and *preserving* are
three kinds of work, requiring for their accomplishment sometimes
only a single preservative fluid, but in most cases two, three, or even
more. As the same fluid often does the work of killing and hardening,
and sometimes of preserving too, it is impossible to divide them into
three classes corresponding to the kinds of work, except by repeating
many of them twice, and some of them three times. While it is there-
fore more convenient to include them all under "preservative fluids,"
as Dr. Mayer has done, it is none the less important to remember what

---

* MT. Zool. Stat. Neapel, ii. (1880) pp. 1–27. We ought long since to have
printed a translation of this paper, but in consequence of a succession of accidents
we have been prevented doing so, notwithstanding that we had a complete
translation made of it soon after it appeared. The abstract we now give is that
(with slight alterations) of C. O. Whitman in Amer. Natural., xvi. (1882)
pp. 697–706, who says " I have added the methods of Dr. Giesbrecht, Dr. Andres
(*infra*), and some others who have worked in the zoological station. Dr. Mayer has
further placed at my disposal such improvements and alterations as he has been
able to make since the publication of his paper. I am also deeply indebted to
Dr. Mayer for advice and generous assistance, for which I wish here to give ex-
pression to my most sincere thanks and grateful appreciation. I am still further
indebted to Dr. Eisig, Dr. Lang, Dr. Andres, Dr. Giesbrecht, Professor
Weismann, and Professor Dohrn, all of whom I have had occasion to consult
with reference to matter contained in this paper." Mr. G. Brook, junr., also
rendered a very useful service to microscopists by publishing a summary in
' Naturalist,' vi. and vii. (1881), parts of which are embodied in the text.

kind or kinds of work each fluid is expected to accomplish. Kleinenberg's picro-sulphuric acid, for instance, now so much used in the Naples Aquarium, is not a hardening fluid. It serves for killing, and thus prepares for subsequent hardening.

1. *Kleinenberg's Picro-sulphuric acid* * :—

Picric acid (cold saturated solution in
    distilled water) .. .. 100 volumes
Sulphuric acid (concentrated) .. .. 2 ,,

Filter the mixture, and dilute it with three times its bulk of water (or for Arthropoda undiluted), finally add as much creosote (made from beech-wood tar) as will mix.†

Objects are left in the fluid three, four, or more hours ; ‡ and are then, in order to harden and remove the acid, transferred to 70 per cent. alcohol, where they may remain 5 to 6 hours. They are next placed in 90 per cent. alcohol, which must be changed at intervals until the yellow tint has wholly disappeared.

The advantages of this fluid are, that it kills quickly, by taking the place of the water of the tissues ; that it frees the object from sea-water and the salts contained in it, and that having done its work it may be wholly replaced by alcohol. In this latter fact lies the superiority of the fluid over osmic and chromic solutions, all of which produce inorganic precipitates and thus leave the tissues in a condition unfavourable to staining. Picro-sulphuric acid does not, like chromic solutions, harden the object, but simply kills the cells.

As this fluid penetrates thick chitine with difficulty, it is necessary, in order to obtain good preparations of larger Isopoda, insects, &c., to cut open the body with the scissors and fill the body-cavity with the liquid by means of a pipette. In larger objects care should be taken to loosen the internal organs so that the fluid may find easy access to all parts.

The fluid should be applied as soon as the body is opened, so that the blood may not have time to coagulate and thus bind the organs together. A large quantity of the fluid should be used (especially when objects with large internal cavities have to be prepared whole), and it must be changed as often as it becomes turbid. The same rule holds good in the use of all preservative fluids. It is well also, especially with larger objects, to give the fluid an occasional stirring up.

In order to avoid shrinkage in removing small and tender objects

---

* Quart. Journ. Micr. Sci., xix. (1879) pp. 208–9. See this Journal, ii. (1879) p. 461.

† Dr. Mayer prepares the fluid as follows :—Water (distilled), 100 vols. ; sulphuric acid, 2 vols. ; picric acid as much as will dissolve. Filter and dilute as above. No creosote is used.

‡ Dr. Mayer's own remarks are :—How long objects should remain in the acid depends of course upon their nature. Usually a few hours is sufficient, but for larger objects and those containing a large percentage of water a longer time is necessary. In some cases a whole day does not produce any injurious effect.

from the acid to the alcohol, it is advisable to take them up by means of a pipette or spatula, so that a few drops of the acid may be transferred along with them. The objects, sinking quickly to the bottom, remain thus for a short time in the medium with which they are saturated, and are not brought so suddenly into contact with the alcohol. In a few minutes the diffusion is finished ; and they may then be placed in a fresh quantity of alcohol, which must be shaken up frequently and renewed from time to time until the acid has been entirely removed.

The sulphuric acid contained in this fluid causes connective tissue to swell, and this fact should be borne in mind in its use with vertebrates. To avoid this difficulty Kleinenberg has recommended the addition of a few drops of creosote, made from beech-wood tar, to the acid. According to Dr. Mayer's experience, however, the addition of creosote makes no perceptible difference in the action of the fluid.

Professor Emery finds the process very useful for embryos of vertebrates and for fishes, but they should not be allowed to remain in the acid more than three or four hours. Although the method is considerably the best for preserving Crustacea as a rule, it will not do for the parasitic species, in which it produces swellings, dissolution of parts of the tissues, &c.

2. *Picro-nitric or Picro-hydrochloric acid.*—Kleinenberg's fluid must not be used with objects (e. g. Echinoderms) possessing calcareous parts which it is desired to preserve, for it dissolves carbonate of lime and throws it down as crystals of gypsum in the tissues. For such objects picro-hydrochloric or picro-nitric acid may be used, prepared as follows :—

Water	100 volumes.	
Nitric acid (25 per cent. N_2O_5)	5	,,
[or hydrochloric acid (25 per cent. HCl)	8	,,]
Picric acid as much as will dissolve.*		

Picro-nitric acid also dissolves carbonate of lime, but it holds it in solution, and thus the formation of crystals of gypsum is avoided. In the presence of much carbonate of lime, the rapid production of carbonic acid is liable to result in mechanical injury of the tissues, hence in many cases chromic acid is preferable to picro-nitric acid.

Picro-nitric acid is, in most respects, an excellent preservative medium, and as a rule will be found to be a good alternative in those cases where picro-sulphuric acid fails to give satisfactory results. Dr. Mayer commends it very strongly, and states that with eggs containing a large amount of yolk material, like those of *Palinurus*, it gives better results than nitric, picric, or picro-sulphuric acid. It is not so readily removed from objects as picro-sulphuric acid, and for this reason the latter acid would be used wherever it gives equally good preparations.

* This mixture is used undiluted.

3. *Alcohol.*—In the preparation of animals or parts of animals for museums or histological study, it is well known that the chief difficulties are met in the process of killing. Alcohol, as commonly used for this purpose by collectors, has little more than its convenience to recommend it. Dr. Mayer calls attention to the following disadvantages attending its use in the case of marine animals :—

(1) In thick-walled animals, particularly those provided with chitinous envelopes, alcohol causes a more or less strong maceration of the internal parts, which often ends in putrefaction.

(2) In the case of smaller Crustacea, e. g. Amphipods and Isopods, it gives rise to precipitates in the body-fluids, and thus solders the organs together in such a manner as often to defy separation even by experienced hands.

(3) It fixes most of the salts of the water adhering to the surface of marine animals, and thus a crust is formed which prevents the penetration of the fluid to the interior.*

(4) This crust also prevents the action of staining fluids, except aqueous solutions, by which it would be again dissolved.

Notwithstanding these drawbacks, alcohol is still regarded at the Naples Aquarium as an excellent fluid for killing many animals designed for preservation in museums or for histological work. In many cases the unsatisfactory results obtained are to be attributed not to the alcohol *per se,* but to the method of using it. Most of the foregoing objections do not, as Dr. Mayer expressly states, apply to fresh-water animals ; and Dr. Eisig informs Mr. Whitman that he has no better method of killing marine annelids than with alcohol. Judging from the preparations which were shown him, and which were all beautifully stained with borax carmine, Dr. Eisig's mode of treatment must be pronounced very successful. The process is extremely simple ; a few drops of alcohol are put into a vessel which contains the annelid in its native element, the sea-water; this is repeated at short intervals until death ensues. After the animal has been thus slowly killed, it may be passed through the different grades of alcohol in the ordinary way, or through other preservative fluids. Objects killed in this manner show no trace of the external crust of precipitates which arises where stronger grades of alcohol are first used. The action of the alcohol is thus moderated, and the animal, dying slowly, remains extended and in such a supple condition that it can easily be placed in any desired position. The violent shock given to animals when thrown alive into alcohol of 40 per cent. to 60 per cent., giving rise to wrinkles, folds and distortions of every kind, is thus avoided, together with its bad effects.

4. *Acid Alcohol.*—In order to avoid the bad effects of alcohol,

* Dr. Mayer first noticed this in objects stained with Kleinenberg's hæmatoxylin, and afterwards in the use of cochineal, where a grey-green precipitate is sometimes produced which renders the preparation worthless. Such results may be avoided by first soaking the objects a few hours in acid alcohol (1–10 parts hydrochloric acid to 100 parts 70 per cent. alcohol).

such as precipitates, maceration, &c., **Dr. Mayer** recommends acid alcohol—

> 97 volumes 70 per cent. or 90 per cent. alcohol,
> 3   „   hydrochloric acid,

for larger objects, particularly if they are designed for preservation in museums. The fluid should be frequently shaken up, and the object only allowed to remain until thoroughly saturated, then transferred to pure 70 per cent. or 90 per cent. alcohol, which should be changed a few times in order to remove all traces of the acid. For small and tender objects, acid alcohol, although preferable to pure alcohol, gives less satisfactory results than picro-sulphuric acid.

Acid alcohol as above prepared loses its original qualities after standing some time, as ether compounds are gradually formed at the expense of the acid.

5. *Boiling Alcohol.*—In some cases among the Arthropods, **Dr. Mayer** has found it difficult to kill immediately by any of the ordinary means, and for such cases recommends boiling absolute alcohol, which kills instantly. For Tracheata this is often the only means by which the dermal tissues can be well preserved, as cold alcohol penetrates too slowly.

6. *Osmic Acid.*—**Dr. Mayer** employs osmic acid as a staining medium for the hairs, bristles, &c., of the dermal skeleton of Arthropods. The lustre of *Sapphirina* is preserved by this acid,[*] and according to Emery, the colour of the red and the yellow fatty pigments of fishes. Van Beneden found osmic acid the best preservative fluid for the Dicyemidæ, and Mr. Whitman's experience leads to the same conclusion.[†]

Although **Dr. Mayer** seldom uses this medium where histological details are required, he observes that in those classes of animals whose bodies are easily penetrated with watery fluids, osmic acid is seldom to be dispensed with.

Bleaching.—It often happens that objects treated with osmic acid continue to blacken, after removal from the acid, until they are entirely worthless, and such results are even more annoying than the difficulties in the way of staining. It has been said that the blackening process can be arrested by certain staining media, but it is certain that picro-carmine will not always do this, as some of Mr. Whitman's preparations of Dicyemidæ show. It is therefore a very important step which **Dr. Mayer** has taken in finding a method of restoring such objects. The method [‡] is as follows :—The objects are placed in 70 per cent. or 90 per cent. alcohol, and crystals of potassic chlorate ($KClO_3$) shaken into the liquid until the bottom of the vessel is covered ; then a few drops of concentrated hydrochloric [§] acid are

---

* See corrosive sublimate, p. 872.

† One of the best objects for testing methods is found in *Phronima sedentaria.* Here the cells and nuclei are so sharply defined that they can be seen in the living animal, and so the effect of a preservative fluid can be easily studied.

‡ A slightly modified form of the method originally given in Arch. f. Anat. u. Physiol. (Du Bois Reymond and Reichert) 1874, p. 321.

§ Nitric acid may be used instead of HCl.

added with a pipette, and as soon as chlorine (easily recognized by its greenish-yellow colour) begins to be liberated, the whole gently shaken. As soon as the bleaching is finished the objects are removed to pure alcohol. By this method Dr. Mayer has been able in half a day to restore large *Pelagia, Carinaria, Rhizostoma,* &c. Small objects generally require a shorter time and less acid. The process can be greatly accelerated by heating on a water-bath.

Using *Sapphirina* as a test-object, Dr. Mayer found that the lustre which characterizes the living animal entirely disappeared by the bleaching process. As this lustre, which has its seat in the epidermis, depends on the interference of light, it is evident that the cells had undergone some change, but a change so slight that the tissues could hardly be said to have been injured for histological purposes ; besides, the removal of the osmic acid leaves the animal in a good condition for staining.

Dr. Mayer's experience with *Sapphirina* appears to support him in the following conclusions in regard to the nature of the action of osmic acid, viz. that the hardening effect of the acid is due to the formation of inorganic precipitates within the tissues. This is made evident by the fact that the animal becomes soft and flexible as soon as these precipitates are removed by bleaching.

This method of bleaching has been used by Dr. Mayer for removing natural pigment. Alcoholic preparations of the eye of *Mysis,* for instance, can be fully bleached *in toto,* but with better success by operating with single sections. To avoid swelling, which is apt to arise by the use of aqueous fluids, staining media of an alcoholic nature should be used.

7. *Chromic Acid.*—Chromic solutions have, in common with osmic acid, the peculiarity of hardening by virtue of the chemical combinations which they form with cell-substances, and all the consequent disadvantages with respect to staining. The use of chromic acid in the Zoological Station of Naples may be said to have been largely superseded by picro-sulphuric acid, corrosive sublimate, and Merkel's fluid, for it is now seldom used except in combination with other fluids.* It is sometimes mixed with Kleinenberg's fluid, for example, when a higher degree of hardening is required than can be obtained by the use of the latter fluid alone. It is a common error to use too strong solutions of chromic acid, and to allow them to act too long. Good results are in some cases obtained when the objects are treated with a weak solution ($\frac{1}{3}$–$\frac{1}{2}$ per cent.) and removed soon after they are completely dead.

8. *Merkel's Fluid.*—

Platinum chloride dissolved in water	..	..	..	1:400
Chromic acid	,,	,,	..	..	..	1:400

* Dr. W. Pfitzner (Morphol. Jahrb., vii. (1882) p. 731) has recently made use of chromic acid followed by (1) osmic acid, or by (2) chloride of gold, formic acid and safranin (or hæmatoxylin) for the demonstration of nerve-terminations.

Flemming believes that chromic acid is one of the most reliable fixing reagents for the karyokinetic figures, and has proved that objects hardened in this acid can be beautifully and durably stained, *ante,* p. 715.

Professor Merkel,* who employed a mixture of these two solutions in equal parts for the retina, states that he allowed from three to four days for the action of the fluid. Dr. Eisig has used this fluid with great success in preparing the delicate lateral organs of the Capitellidæ for sections, and recommends it strongly for other annelids. Dr. Eisig allows objects to remain 3–5 hours in the fluid, then transfers to 70 per cent. alcohol. With small leeches Mr. Whitman has found one hour quite sufficient, and transfer to 50 per cent. alcohol.

9. *Corrosive Sublimate.*—Prompted by a statement found in an old paper by E. Blanchard,† Dr. Lang began experimenting with corrosive sublimate as a medium for killing marine Planarians, and his marked success led him and others to employ the same with other animals. In most cases Dr. Lang now uses a saturated solution of corrosive sublimate in water. A saturated solution in picro-sulphuric acid, which in some cases gives better results if a little acetic acid (5 per cent. or less) is added, is also used.‡ Blanchard's mode of treatment was to mix a quantity of the aqueous solution with the sea-water, and thus poison the animals. Dr. Lang, on the contrary, removes the sea-water so far as possible before applying the solution. With Planarians he proceeds in the following manner :—

The animal is laid on its back and the water removed with a pipette, the solution being then poured over it, it dies quickly and remains fully extended. After half an hour it is washed by placing it in water and changing the water several times during thirty minutes. It is next passed through 50 per cent., 70 per cent., 90 per cent., and 100 per cent. alcohol. In two days it is fully hardened, and should then be stained and imbedded in paraffin as early as possible, as it is liable to become brittle if left long in alcohol. The time required by the corrosive sublimate varies with different objects, according to size and the character of the tissues. As a general rule, it may be said that objects should be removed from the fluid as soon as they have become thoroughly saturated by it. In order to kill more quickly than can sometimes be done at the ordinary temperature, the solution is heated, and in very difficult cases may be used boiling.

Corrosive sublimate has been used with success by Dr. Lang and others in the following cases :—Hydroids, Corals, Nemertines, Gephyreans, *Balanoglossus,* Echinoderms, *Sagitta,* Annelids, Rhabdocœla, Dendrocœla, Cestodes, Trematodes, embryos and adult tissues of Vertebrates and, according to Mayer and Giesbrecht, Crustacea with thin chitinous envelopes, e. g. *Sapphirina,* Copepods and larvæ of Decapods. With the Arthropoda good results have not been obtained.

* 'Ueber die Macula lutea des Menschen,' &c., Leipzig, 1870, p. 19.
† Ann. Sci. Nat. Zool., viii. (1874) p. 247.
‡ These solutions are given in Zoolog. Anzeiger, ii. (1879) p. 46. The original solution (Zoolog. Anzeiger, i. (1878) pp. 14–15, this Journal, i. (1878) p. 256) now little used, stood thus :—Distilled water, 100 parts; common salt, 6–10 parts; acetic acid, 5–8 parts; corrosive sublimate, 3–12 parts; alum (in some cases) ½ part.

The two great advantages of Dr. Lang's method are (1) that animals so treated are easily stained, and (2) they are killed so quickly that they are left, in most cases, in a fully extended condition. Hot corrosive sublimate kills leeches so instantaneously that they often remain in the attitude assumed the moment before the fluid is poured over them. The colour, however, is not so well preserved as when killed with alcohol, or even with weak chromic acid.

It should be remembered that objects lying in a solution of corrosive sublimate must not be touched with iron or steel instruments; wood, glass, or platinum may be used.

II. STAINING.—It has gradually become a settled custom in the Zoological Station to mount microscopical preparations in balsam wherever this can be successfully done; and to avoid, as much as possible, the use of aqueous media, both in mounting and staining. The disadvantages often arising from the use of these media in staining alcoholic preparations include the tearing asunder of fragile tissues caused by the violent osmosis set up on transferring an object from alcohol to an aqueous solution; swelling, the effects of which cannot always be fully obliterated by again transferring to alcohol; and maceration, which is liable to result where objects are left for a considerable time in the staining liquid (as Beale's carmine). These may all be avoided by using alcoholic solutions. Objects once successfully hardened may be left in such solutions for any required time, and when sufficiently stained, be washed in alcohol of a corresponding strength, and then passed through the higher grades without being exposed to water from first to last. As a rule, alcoholic dyes work quickly, and give far more satisfactory results than can be obtained with other media. They penetrate objects more readily, and thus give a more uniform colouring where objects are immersed *in toto*. Even chitinous envelopes are seldom able to prevent the action of these fluids.

It is not, however, to be denied that non-alcoholic dyes may often do excellent work, and, in certain cases, even better than can be otherwise obtained. In the case of the Turbellaria, Dr. Lang has found picro-carmine to be one of the best staining agents, and this has been Mr. Whitman's experience with Dicyemidæ. As Dr. Mayer has remarked, the swelling caused by aqueous staining fluids is not always an evil, but precisely what is required by some objects after particular methods of treatment.

From experiments recently made, Dr. Mayer has found that dyes containing a high percentage of alcohol, stain more diffusely than those of weaker grades, from which he infers that strong alcohol robs, to a certain extent, the tissues of their selective power, and renders them more or less equally receptive of colouring matter.

1. *Kleinenberg's Hæmatoxylin.*[*]—1. To a saturated solution of chloride of calcium [†] in 70 per cent. alcohol, add a little alum and filter.

---

[*] May be used after all hardening fluids.

[†] Chloride of calcium, according to Kleinenberg, has no other use than to strengthen the osmotic action between the hæmatoxylin solution and the alcohol contained in the tissues. As chloride of calcium and alum give a precipitate of gypsum, it would probably be better to use chloride of aluminium.

2. One volume of No. 1 mixed with 6 to 8 volumes of 70 per cent. alcohol.

3. At time of using pour into No. 2 as many drops of a concentrated solution of crystallized hæmatoxylin in absolute alcohol as suffice to give the required depth of colour. A good solution should be violet inclining a little to blue. The red tinge that arises after the fluid has stood for some time, indicates that it has become slightly acid, in which condition it is unfit for use. To restore its proper colour, it is only necessary to open a bottle of ammonia over the mouth of the bottle holding the hæmatoxylin in such a manner that a very small quantity of the gas will mix with the fluid. If too much ammonia gas be added, a precipitate is produced which spoils the fluid.

If the colour appears too strong, the fluid may be diluted with solution No. 1.

Before immersing objects in this fluid, great care should be taken to free them from the least trace of acid by frequently changing the alcohol. If this is not done thoroughly, the acid left in the preparation will sooner or later cause the colour to fade; and such results have led to the erroneous conclusion that hæmatoxylin will not give durable preparations. Dr. Mayer has found that the fading is entirely due to the presence of acid, and that with proper precautions the staining is permanent.

Small objects are best stained in a weak solution, which colours more slowly but with greater clearness than stronger solutions. After staining, Kleinenberg transfers objects to 90 per cent. alcohol. In case of over-staining, the colour may be partly removed by adding a little *oxalic acid* or *hydrochloric acid* ($\frac{1}{2}$ per cent. or less) to the alcohol containing the objects. The acidulated alcohol is allowed to work until the colour is slightly reddened. On transferring to pure alcohol the colour passes again into a permanent blue-violet.

2. *Mayer's Cochineal Tincture.*—This medium is very similar in most respects to hæmatoxylin, and is made by soaking 1 gramme powdered cochineal in 8–10 ccm. 70 per cent. alcohol for several days, and then filtering.

The clear deep red fluid thus prepared may, like hæmatoxylin, be used in all cases where it is desirable to stain with an alcoholic solution, and will be found particularly useful for objects that, by reason of the thickness of the walls or other peculiarities, are not easily penetrated by the ordinary aqueous solutions of carmine. It is particularly suited for the Arthropoda, whose chitine only allows the dye to penetrate with difficulty.

It is necessary, before immersing larger objects in this fluid, to leave them a short time in 70 per cent. alcohol, otherwise there may be a precipitate. The time required for staining will vary from a few minutes to even days, according to the nature and size of the object. For small objects, such as very thin sections, minute worms, Protozoa, the lower Arthropoda, &c., an immersion of a quarter of an hour, sometimes even less, is usually sufficient. With larger objects requiring considerable time, it is important to use a large quantity of the fluid, otherwise the amount of colouring stuff in solution might

not suffice to give the proper depth of colour. Small and delicate objects, on the other hand, may be most successfully treated with a solution which has been diluted with 70 per cent. alcohol, or one which has been weakened by previous use. It is always necessary to free the tissues, after staining, from the surplus dye; and this may be done by washing in 70 per cent. alcohol, which must be changed until it shows no colour. This process requires, for larger objects, considerable time and alcohol, but may be hastened by using the alcohol slightly warm.

The colour ultimately assumed by objects treated with cochineal tincture varies much, and depends partly on the reaction of the tissues themselves, partly on the presence or absence of certain salts. It is certainly one of the best recommendations of this staining agent that varying with the nature of the object and its mode of treatment both before and after staining, it gives such an extraordinary diversity of results. On account of the great variety of substances contained in the dried dye-stuff, it is evident that the composition of the tincture must vary according to the strength of the alcohol employed as a solvent. Solutions in 90 per cent. or 100 per cent. alcohol have a light red colour, and stain too diffusely to have any practical value. The weaker the alcohol the stronger the tincture, and the stronger the alcohol the more easily it penetrates objects; the grade of alcohol may therefore be selected with reference to two points, depth of colour and readiness of penetration; 70 per cent. or 60 per cent. is recommended by Dr. Mayer as combining both these qualities in a very favourable degree. It is important to remember that whatever be the strength of the solution, a precipitate will always be produced if an alcohol of a different grade, whether higher or lower, be mixed with it. It is evident, then, that a tincture of any given strength contains substances that are insoluble in any other grade of alcohol, and this explains why superfluous colouring matter can only be removed from objects by the aid of alcohol of precisely the same degree as that of the tincture.

Over-staining, which seldom occurs, may be easily corrected by the aid of acid alcohol ($\frac{1}{10}$ per cent. hydrochloric acid, or 1 per cent. acetic acid). Acid makes the tincture lighter, more yellowish-red, while the addition of ammonia and other caustic alkalies changes it to deep purple. Still more important is the fact that salts soluble in alcohol give a blue-grey, green-grey, or blue-black precipitate. For example, if a piece of cloth that has been dyed in cochineal and washed be treated with an alcoholic solution of a ferric or a calcic salt, it will assume a more or less deep blue colour.

As the salts present in the living organism are seldom, if ever, fully removed by preservative fluids, but in some cases even increased, it will often happen that an object, though put in the red fluid, comes out blue, precisely as when stained with hæmatoxylin. Such a result cannot, however, be obtained where the tissue is in the presence of acids, or free from inorganic salts; under these conditions the colour is always red. It is not possible, therefore, to know what colour an object will ultimately present.

Usually, all Crustacea with thick chitinous parts are stained red, and most other animals blue; so that, for instance, the Vorticellidæ, which are parasitic on the Amphipoda, can be at once recognized as foreign bodies. Very often the different tissues of one and the same object present unlike colours. In the embryos of *Lumbricus*, Kleinenberg found the walls of the blood-vessels red, their contents dark-blue. Glandular tissues, or their contents, are frequently stained grey-green, and on this account are easily recognizable.

Objects when previously treated with chromic or picric solutions, or with alcohol, usually stain without difficulty; but osmic acid preparations should be bleached before staining. Cochineal does not colour so intensely as hæmatoxylin, and hence the latter often gives more satisfactory results in the case of large objects stained *in toto.*

As before pointed out, alcohol causes the salts contained in sea-water to be precipitated, thus forming a crust on the exterior of the animal, which interferes with the staining process. It is therefore necessary to treat marine animals that have been preserved in strong alcohol, with acid alcohol (1–10 parts hydrochloric acid to 1000 parts 70 per cent. alcohol), and then carefully wash in pure 70 per cent. alcohol before staining with cochineal.

3. *Carmine and Picrocarmine.*—Aqueous solutions of staining media are generally only used when alcoholic cannot be employed. The interpretation of the results obtained by carmine staining is not always satisfactory. For instance, in his work on the nervous system of *Aquilla*, Bellona describes the peculiar crescent-like structures in the ganglion cells. Dr. Mayer is of opinion that these are entirely artificial productions, and owe their origin to the carmine (Beale's) solution in which they were stained, for with careful preparation they do not appear. Picrocarmine is more certain in its results, and in some cases will give better specimens than can be obtained by any other medium. In commerce it often contains too much picric acid, and it is better to prepare it oneself in the following manner :—

To a mixture of powdered carmine (2 g.) with water (25 ccm.), while heating over a water-bath, add sufficient ammonia to dissolve the carmine. The solution may then be left open for a few weeks (Mayer) in order that the ammonia may evaporate; or the evaporation may be accelerated by heating (Hoyer). So long as any ammonia remains, large bubbles will form while boiling, but as soon as the free ammonia has been expelled, the bubbles will be small and the colour of the fluid begin to be a little lighter. It is then allowed to cool, and filtered. To the filtered solution is added a concentrated aqueous solution of picric acid (about four volumes of the acid to one of the carmine solution). The addition of the acid should cease before a precipitate begins to form.

In order to protect this fluid against changes attributed to bacteria by Hoyer,[*] Dr. Mayer places a small crystal of thymol in the con-

* Hoyer, "Beitr. z. histolog. Technik.," Biol. Centralbl., ii. (1882) pp. 17–19.

taining bottle; Hoyer uses choral-hydrate (1 per cent. or more) for the same purpose.*

4. *Acetic Acid Carmine.*†—Pulverized carmine added to a small quantity of boiling acetic acid (45 per cent.) until no more will dissolve; filtered and diluted to about 1 per cent. for use.

Flemming used the concentrated solution.

5. *Grenacher's Carmine Solutions.*‡ — (i.) *Alum Carmine.* — An aqueous solution of alum (1–5 per cent., or any degree of concentration) boiled with ½–1 per cent. powdered carmine for 10–20 minutes; allowed to cool, then filtered.

With the addition of a little carbolic acid the fluid will keep for years. It colours quickly, and nuclei more strongly than other parts. Objects washed in water after staining.

(ii.) *Acid Borax Carmine.*—*a.* An aqueous solution of borax (1–2 per cent.) and carmine ($\frac{1}{2}$–$\frac{3}{4}$ per cent.) heated till the carmine is dissolved.

b. Acetic acid added by drops to solution *a*, while shaking, until the colour is about the same as that of Beale's carmine.

c. Solution *b* left standing twenty-four hours, then turned off and filtered.

This solution, which is a modification of Schweigger-Seidel's acid carmine, is not recommended for colouring *in toto*. It colours sections in ½–3 minutes diffusely, and hence, after washing in water, they are placed for a few minutes in alcohol (50 or 70 per cent.) to which a drop of hydrochloric acid has been added; then transferred to pure alcohol.

(iii.) *Borax Carmine.*§—*a.* An aqueous solution of borax (4 per cent.) and carmine, heated till the carmine is dissolved.

b. Solution *a* mixed with 70 per cent. alcohol in equal parts, left standing twenty-four hours and filtered.

This fluid may be used for colouring objects *in toto*. After staining, the objects are to be washed in 35 per cent. alcohol, to which a little hydrochloric acid has been added (4–6 drops to 100 ccm.), and allowed to remain here until the colour has been sufficiently removed. They are next passed through successively higher grades of alcohol for hardening.

(iv.) *Alcohol Carmine.*—A teaspoonful of carmine dissolved, by heating about ten minutes, in 50 ccm. of 60–80 per cent. alcohol, to which 3–4 drops of hydrochloric acid have been added, then filtered.

---

* Dr. Lang's picro-carmine and eosin method for Planarians, see this Journal, ii. (1879) p. 163, is also referred to. Dr. Mayer does not expect any particular advantage from its application to Arthropods.

† Schneider, Zool. Anzeig., 1880, p. 254.

‡ Grenacher, "Einige Notizen z. Tinctionstechnik," Arch. f. Mikr. Anat., xvi. (1879) p. 463. None of these solutions should be used where calcareous parts are to be preserved.

§ Dr. Mayer prepares, for some purposes, borax carmine of 50, 60, or 70 per cent. That of 70 per cent. contains little carmine, but is well adapted to staining delicate objects that would suffer if exposed to weaker solutions. Boiling alcohol (50 per cent. or 60 per cent.) dissolves about 1 per cent carmine and 1 per cent. borax.

Objects coloured in this fluid should not be washed in water, but in alcohol of a grade corresponding to that of the solution.

For diluting alcoholic solutions of carmine, alcohol of the same strength must always be used.

6. *Aniline Dyes.*—As a rule, aniline colours and the many others obtained recently from tar by chemical processes, cannot be used for staining objects *in toto*, and are therefore not much employed in the Zoological Station. In very small objects and sections already cut, very excellent results can be obtained by the methods developed by Böttcher,[*] Hermann,[†] Flemming [‡] and others; for here diffuse staining may generally be avoided by first over-staining and then withdrawing the colour to any desired extent by means of alcohol. But to obtain satisfactory results, the sections must be thin enough to allow uniformity of action both to the colouring and the decolouring agent. It is evident that the process cannot be similarly controlled in larger objects, particularly where a dye is used, which, like most of those under consideration, is quickly extracted by alcohol, for in this case the colour would be removed from the superficial layers more rapidly than from the deeper ones, so that a uniform precision of colour would be impossible. In this respect,

a. Bismarck-brown forms an exception. The preparation of this dye, introduced by Weigert,[§] is extremely simple:—

A saturated solution is made by dissolving the powder in boiling water or weak alcohol, or, according to Mayer, in 70 per cent. alcohol.[||] The solution should be used undiluted, and requires to be filtered from time to time. It colours very quickly objects hardened in alcohol or chromic acid.

b. Safranin.—1 part safranin dissolved in 100 parts of absolute alcohol; after a few days 200 parts of distilled water is added.

Dr. Pfitzner,[¶] from whom the above formula is taken, recommends this solution as one of the best for staining nuclei. It is cheap, easily prepared, acts quickly, and stains only the nuclei. It works best with chromic acid preparations, from which the acid has been removed as much as possible.

Unless therefore it is desired to differentiate membranes or display the various stages of ossification this group may be dispensed with.

III. INJECTING.—Professor Emery, who has lately studied the methods of injection, recommends the following:—

a. For injection of *thick carmine* he follows the prescription of Ranvier, in his 'Traité d'histologie technique,' but neutralizes the mass in a more simple way. Acetic acid is added by drops until the

[§] Arch. f. Mikr. Anat., xv. (1878) p. 258.

[||] According to Flemming, it may also be dissolved in dilute acetic acid.

[¶] Morph. Jahrb., vi. pp. 478–80, and vii. p. 291.

smell of the ammonia becomes very faint. The reaction of the vapour is then tried with litmus paper. Sufficient acid has been added when the litmus paper begins to get red. Often, on stirring, the alkaline reaction will return, but this must be removed with another drop of acetic acid. In use it will be found that with a neutral or slightly acid mass, a diffusion of the medium through the cell-walls is scarcely likely to occur.

b. As a cold fluid mass, Emery recommends a 10 per cent. carmine solution prepared with ammonia, to which, while continually stirring, acetic acid is added until the carmine begins to be precipitated, and the liquid has a blood-red colour. The clear liquid only must be used, and after injection, the objects must be at once placed in strong alcohol, to fix the carmine.

c. For injecting the capillaries, good results are often obtained by gradually mixing 10 per cent. carmine solution with acetic acid, until part of the carmine is precipitated. The solution must be shaken shortly before use, only allowing it to settle for a few minutes, so that the coarser grains do not get into the syringe. In injections from the arteries a considerable quantity of fine sediment remains in the capillaries, while only a light fluid enters the veins. Thus the veins can easily be distinguished from the arteries, which are dyed dark red.

IV. MOUNTING.—The great object aimed at, in preparing permanent preparations for the Microscope, is to entirely get rid of the water in the tissues of the object, and supplant it by a preservative medium. Hence, at Naples the aqueous mounting media such as glycerine, glycerine jelly, acetate of potash, &c., are in little favour. After the water has been forced from the object and supplanted by alcohol, the process is usually completed by passing through oil of cloves, and mounting in balsam. Usually there is little trouble with this method. The oil of cloves, or other similar oil, is slightly heated, and as a rule it will penetrate the tissues without trouble. With larger objects, however, and particularly those with thin but not easily permeable walls, the alcohol will often leave before the oil can enter, and there will be a collapse of the walls. *Creosote* has been used to prevent this shrinking, but it appears to render no permanent good. Dr. Mayer meets the difficulty in the larger objects by making an insertion with a fine pair of scissors in an unimportant part of the body-cavity, so as to allow the oil to enter at once. This answers very well, and can be used with very small objects, such as *Auricularia* and other larvæ, if a fine flattened needle be used. If this should fail, and especially when the number of objects to be transferred to balsam is large, the alcohol may be supplanted gradually. Dr. Mayer has thus prepared very young larvæ of Echinoderms. The specimens were taken up in a capillary tube, with the surrounding alcohol, and then placed in a tube, with a drop of oil of cloves at the bottom. After the lapse of half-a-day the larvæ, which at first swam on the top of the oil, had gone to the bottom of it, and could be easily removed again by the same tube. Objects may be left in oil of cloves for months without any apparent detriment.

Recently Kleinenberg has recommended the use of *colophonium* instead of Canada balsam. The solution in absolute alcohol is not suitable, as under certain circumstances the finished preparations will show large bundles of crystals. Turpentine should be used as a solvent; this, however, has the disadvantage that the preparations dry very slowly. The solution in chloroform seems to answer well, but must be filtered before use. Further experience is required with this medium before its use can be strongly recommended.

A solution of *sandarac* in absolute alcohol, which at first appeared to answer well, has not, on further trial, proved satisfactory.

V. DISSECTING.—For the dissection of single organs, fresh animals are generally placed in dilute alcohol, or a weak chromic solution. But the tissues are liable to suffer from maceration in these fluids, and hence, where it is important that the tissues should be well preserved, it is advisable to use picro-sulphuric acid, regardless of the injurious effects of the same on the dissecting instruments. The fluid should be changed as soon as it gets thick and the preparation well washed in alcohol afterwards. The hardening capacity of the picro-sulphuric acid is extremely slight, but may be strengthened by the addition of chromic acid. Preparations thus obtained, and subsequently treated with alcohol, staining fluids, &c., should be transferred to creosote for further dissection, as the transparency induced by this medium will greatly facilitate the work.*

VI. IMBEDDING.— For section-cutting, objects are usually imbedded in paraffin. By low temperature, as in winter, it is necessary to work with a softer paraffin than is required for summer. Instead of softening by an admixture of lard, as generally done, it is better to use a paraffin which becomes soft in summer, on account of its containing liquid hydrocarbons, and is preferable to lard as it is not liable to become rancid.

Preparatory to imbedding, the objects are removed from absolute alcohol † to creosote, clove oil, or chloroform, and left until they become thoroughly saturated. The penetration of the clarifying fluid may, in some cases, be advantageously hastened by warming a little. They are next placed in soft paraffin, heated to about 50° C. over a water bath, and allowed to remain for an hour or so. The soft paraffin is then turned off and replaced by a mixture of hard and soft paraffin,‡ heated to about 50° C. After remaining for half-an-hour or less in the harder paraffin, kept at a steady temperature, they are ready for imbedding. For this purpose a small paper box may be used; or, much better, a box made of two pieces of type-metal, as used in Professor Leuckart's laboratory. As will be seen from Fig. 162, each

---

* In the original paper Dr. Mayer speaks not of creosote, but of oil of cloves. The brittleness which is caused by it is in most cases advantageous, but can easily be reduced by the addition of creosote. The tendency to collect in small drops which is peculiar to oil of cloves may be counteracted by the addition of oil of bergamot.

† In many cases a lower grade of alcohol will suffice.

‡ The ratio of combination must be determined by experiment, since it will depend on the quality of the paraffin and the temperature; two parts of hard to one of soft work very well for the winter temperature of Naples.

piece of metal has the form of a carpenter's square, with the end of the shorter arm triangularly enlarged outward. A convenient size will be found in pieces measuring 7 cm. (long arm) by 3 cm. (short arm), and 7 mm. high. With such pieces a box may be constructed at any moment by simply placing them together on a round plate of glass, which has previously been wet with glycerine and gently warmed. The area of the box will evidently vary according to the position given to the pieces, but the height can be varied only by using different sets of pieces. In such a box the paraffin may be kept in a liquid state by warming now and then over a spirit-lamp, and small objects be placed in any desired position under the Microscope.

It is well to imbed in a thin layer of paraffin, so that the object, after cooling, may be cut out in small cubical blocks, which may be easily fixed, for cutting, to a larger block of hard paraffin.

Fig. 162.

Only in the case of very delicate objects is imbedding in wax and oil after Brücke's plan to be preferred. White of egg has not proved as permanent as might be desired. Gelatine is a convenient imbedding medium, and Dr. Mayer has devised a process by which it is deprived of its elasticity. It is allowed to soak as usual in water, then heated and $\frac{1}{4}$ to $\frac{1}{2}$ a volume of castor oil added, shaken well, and shortly before getting cold pour the mixture into a bowl. When afterwards all the castor oil has been extracted by 90 per cent. alcohol the gelatine remains as a fine porous matter, a sort of artificial pith, and is at once ready for use. It must not of course be exposed too long to the air as this would soften it. Under the Microscope this form of gelatine is less troublesome than lilac pith and has the advantage that it can be produced in any size and always even.

VII. Cutting.—Objects are cut dry with a microtome, and the rolling of the sections may be prevented by holding a thin narrow spatula over the edge of the knife while cutting. The spatula may be made of brass, or of paper fastened to a flattened needle. The spatula should be bent slightly, and the convex face held over the paraffin without pressure. A small brush, slightly flattened, is used for the same purpose in Leipzig.

Andres' Methods of treating Actiniæ.* — Among the various methods employed by Dr. Andres in killing the Actiniæ, the three following, given in the order of their excellence, are said to have worked most satisfactorily :—

A. *Corrosive sublimate.*—With small animals a hot solution, used in the manner recommended by Dr. Lang, gives good results; with
* Atti R. Accad. Lincei, v. (1880) p. 9.

larger animals, where this mode of treatment fails, the fluid must be injected. The cannula of a glass syringe, filled with the hot fluid, is inserted into the mouth at the moment it opens, which act habitually follows on gently touching the lip. After injecting, the hot solution is poured into the glass containing the animal and a small quantity of sea water.

If the operation is cleverly performed, the animal remains fully expanded, as the mechanical pressure of the injected fluid prevents contraction.

After from five to fifteen minutes the animal is washed in distilled water, and allowed to remain twelve hours in 50 per cent. alcohol,* then passed through the higher grades of alcohol. Borax-carmine and hæmatoxylin used for staining.

B. *Glycerine and Alcohol.*†—

Glycerine ..	..	..	..	20 parts.
Alcohol (70 per cent.)	..	..	40 „
Sea water ..	..	..	..	40 „

This mixture, poured very slowly into the containing glass, often gives very good results, both for anatomical and histological purposes.

C. *Nicotine and Tobacco Smoke.*—a. A solution of nicotine (1 g.) in sea water (1 l.), conducted into the vessel containing the animal fully expanded in a half litre of sea water, by means of a thread sufficiently large to empty the flask holding the nicotine solution in the course of twelve hours.

b. The vessel containing the animal in an extended condition, covered by a bell-jar in which tobacco smoke is confined, until the animal becomes completely benumbed.

After being deprived of sensibility by either of these methods, the creature may be killed in corrosive sublimate, or in picro-sulphuric acid.

D. Dr. Andres finds that in the use of chloroform, dropped slowly into the water, or administered in form of vapour, maceration usually sets in before the power of contracting is lost. Good preparations of the internal parts may be obtained by injecting a weak solution of osmic acid. The method of freezing has also been employed with some success. For this purpose three vessels are placed one within the other, the central one containing the *Actinia*, the middle one ice and salt, and the outer one cotton.

The ice containing the congealed animal is dissolved in alcohol or an acid.

E. *Maceration.*—It is often important to see the cells of a tissue *in situ* before freeing them with needles. In such cases Dr. Andres proceeds as follows:—

1. Killed with corrosive sublimate.
2. Left in 25 per cent. alcohol twenty-four hours.

* A little camphor (1–100 ccm.) added to the alcohol will facilitate the removal of the sublimate.
† This method originated with S. Lobianco.

3. Soaked for a short time in a very thin solution of gum arabic then in a somewhat thicker solution, and finally imbedded in a very thick solution.

4. Hardened in 90 per cent. alcohol.

5. Thick sections prepared for dissection with needles. The sections are placed on a slide in water, which dissolves the gum.

Flemming's further Method for Staining Nuclei.* — In his recent researches on karyokinesis, W. Flemming states that he obtained serviceable staining of nuclei in the following ways :—

1. Living eggs of Echinoderms coloured on the slide, either with safranin or aniline dyes, followed by acetic acid (1 per cent.) which is allowed to flow under the cover and thus replace the staining medium, or with acetic acid carmine (after Schneider), used undiluted. The last mentioned staining agent causes swelling, but still gives the typical features of the karyokinetic figures.

2. Eggs first hardened in strong nitric acid (40–50 to aq. dest. 60–50), then washed in distilled water until the yellowish colour, due to the presence of the acid, disappears. Coloured with acetic acid carmine.

Iodine-green and Methyl-green.†—Dr. M. Flesch calls further attention to the suitability of the combination of the green with red staining matters. He has excellent preparations of cartilage, skin, and glands hardened in Müller's fluid and alcohol, and stained with methyl-green, and afterwards with picrocarmine. If the colour is not so beautiful as in the case of objects stained with carmine and hæmatoxylin, it is nevertheless very useful, as it is, he believes, easy to preserve, and moreover it gives very sharp differentiations.

Dr. Flesch uses an aqueous solution of commercial methyl-green diluted until the section in a watch-glass is still recognizable on a bright ground.

Preparation of Epidermis.‡—W. Pfitzner prepares the epidermis of tadpoles by first hardening in chromic acid, and making fine sections with the Thoma microtome of a piece as free as possible from pigment, imbedded in elder pith ; the best thickness for the sections is ·01 to ·015 mm. The sections are washed for at least thirty minutes in distilled water to remove the chromic acid.

Pfitzner has three methods of mounting, either of which may be employed, with various modifications :—

1. Staining. *a.* With saffranin, mount in dammar. *b.* With hæmatoxylin, mount in dammar ; or, *c.* As *b,* but mount in glycerine.

2. Gold treatment :—Treatment with 1 per cent. solution of gold chloride, with a trace of hydrochloric acid, for 15 to 30 minutes, in the dark ; the sections are then carefully washed and exposed to daylight for 12 to 24 hours in a 5 per cent. solution of formic acid,

---

* Arch. f. Mikr. Anat., xx. (1881) p. 1. Cf. Amer. Natural., xvi. (1882) p. 780. See also Flemming's earlier method, *ante,* p. 715.

† Zool. Anzeig., v. (1882) pp. 554–5.

‡ Morpholog. Jahrb., vii. (1882) pp. 731–2. See also *ante,* p. 871.

and then carefully washed again and mounted (*a*) simply in glycerine, or (*b*) in dammar, after staining with saffranin.

The delicacy of the sections necessitates the employment of good daylight, and illumination from below in their manipulation; the latter end may be attained by employing as working stage a cigar box, from which the front side has been removed, putting a piece of glass on the top, and an oblique mirror inside. Great care must be taken not to allow contact between the sections when made, as they would then probably become entangled.

Unpressed Mounting.*—Under this heading Mr. A. W. Stokes describes the mounting of the tongue of a blow-fly " without pressure," so that its true shape is preserved, a halfpenny test-tube being all the preparing apparatus required.

Into this test-tube place the fly's head, and fill the tube half-full with a solution of soda and potash. Stand the tube in boiling water, and leave it on the hob of a fire to keep hot till morning. Then examine the head and see if it looks almost transparent; if not, pour off the soda solution and add a fresh supply, and again keep the tube hot till the object becomes semi-transparent. Now pour off the solution and add hot water, in a few minutes emptying it out and adding some more:—Repeat this at least three times, and finally leave the last quantity of water on the object for an hour to cool. Next pour off all the water and replace it with spirit of wine; methylated spirit, if strong, will do sufficiently well. Heat this by immersing the tube in a vessel of hot water for one minute; then take it out, cork it up, and leave it for one hour.

So far we have, by means of the soda-solution, destroyed all the flesh and fat tissues, leaving only the cuticle and internal organs, such as the tracheæ, &c. In doing this, we have filled up most of the few natural air-spaces with soda-solution, which, however, being a somewhat dense fluid, would not enter many of the narrow tracheal tubes. Then with water we replaced the soda-solution, and washed away the parts destroyed thereby. On replacing the water by alcohol, a still less dense fluid, more of the finer air-spaces are penetrated and the air driven out; there are still, however, some tubes too minute even for alcohol rapidly to enter. So now we pour off the spirit, and add ether instead, which answers a double purpose; it enters the very minutest passages, displacing the contained air, and it also dissolves the globules of fat left unsaponified by the soda-solution. After leaving the ether for fifteen minutes in the corked tube, and shaking it once or twice, we pour it off and add turpentine; and then in ten minutes time the head is ready for mounting in Canada balsam or dammar.

If so mounted, however, it will be very difficult to see much of the finer internal structure, since these media render some parts far too transparent; and hence some of the glycerine media are preferable. In such cases, after pouring off the ether, add alcohol, and at the end of fifteen minutes replace the alcohol with cold water, and

* Journ. Post. Micr. Soc., i. (1882) pp. 129–35.

leave for fifteen minutes more. Then the water may be poured off, and the mounting-fluid, whether glycerine, carbolic-acid, gelatine, Goadby's or Thwaites' fluid, may be added. The object, if mounted in any of these, will have a far more natural appearance, and show more plainly the finer structures, than if mounted in Canada balsam. The times mentioned above are those it is *necessary* in most cases to wait, but longer intervals would often be preferable. If we are busy the tube and its contents may be left at any stage of the proceedings for days, with a certainty that the object will only benefit by the delay, *except* in the case of the soda-solution. It is not necessary to use distilled water, though it is better to do so ; but whatever water is used, it should be just freshly boiled and be used hot. Cold unboiled water contains a large quantity of air, and if used in that state will certainly impart air to the object instead of helping to extract it.

The soda or potash solution is made by adding solid potash or soda to eight times its weight of boiling water, and the only expense of the process is for the tube, soda, alcohol, and ether—a pint of each of the latter will prepare some thousands of specimens.

The same system will answer for sections of wood, small seed-vessels, leaves, &c., only they must first be decoloured by pouring sodic hypochlorite into the tube, then, after well washing with water, the rest of the process may be followed as before, leaving out entirely the use of the soda-solution. The great difference is in the matter of speed, vegetable preparations being made far more rapidly. It is possible to cut a dozen sections from a living branch, bleach, stain, and mount them in Canada balsam or glycerine-solution, and finally, ring and label them, all within the hour.

Should any of the preparations—the blow-fly's head, for instance —become too colourless and transparent, all we have to do is to stain them by the addition of a few drops of an alcoholic solution of some colouring matter (logwood answers well) to the alcohol in the tube. The subsequent use of ether will fix the colour.

Usually, after this treatment, the object will be found to be quite clean ; but if not, it should be gently brushed with a camel-hair pencil while in the turpentine or glycerine fluid. The wings of many insects are partially destroyed during the process, but since these can, if desired, be easily mounted separately, this is not of very great importance.

Directions are also given for mounting the object as above prepared in cells, the use of vulcanite rings being recommended.

Staining with Magdala-red.[*]—Dr. C. Nörner refers to the fact that picrocarmine (Ranvier's) affects different classes of animals very differently. Tape-worms, for example, redden very quickly, while other worms, like the Nematodes, take very gradually a yellowish tinge, because in their case the picric acid takes effect first and the carmine only after a longer time. Mites are also affected variously—some become yellow, others red, and others perhaps remain colourless. Magdala-red is not open to these objections, and

* Arch. f. Mikr. Anat., xxi. (1882) pp. 354-5.

is an exceedingly useful staining medium, because it answers all requirements in an equally favourable way. It possesses a marked differentiating power, and even surpasses picrocarmine in this excellent quality. It colours all tissues uniformly, whether they are fresh or are taken out of alcohol or chromate of potash. What is most important is that the differentiating power is well manifested in botanical preparations, in which each tissue takes a special tint. Care however must be taken that the sections remain only a few minutes in the solution, because it stains with remarkable intensity. For the examination of sieve-tubes (preserved with so much difficulty) Magdala-red will doubtless be very suitable. The vessels of the plerom are very clearly distinguished from the periblem, &c. The lower fungi also, such as *Mucor, Penicillium, Aspergillus*, &c., also take a beautiful colour, like histological sections. An exceedingly satisfactory result is likewise obtained with parasites (mites, worms, &c.). A further advantage is that this dye has a great capacity of resistance to potash, and thus, if required, specimens can be first stained and then treated with potash. For double staining it does not seem to be suitable, as it destroys the other colour.

The author adds, " whether it does not possess the same disadvantage as hæmatoxylin and other aniline colours, and disappears from the preparation after a time, and is therefore unstable, I am not yet able to determine."

Preparing Fossil Foraminifera, Spicules, &c.*—In a second paper † Mr. C. Elcock gives directions for preparing fossil Foraminifera. The material from which they may be most easily prepared is chalk powder, many ways of doing which are recommended by text-books, but all unsatisfactory in practice.

The only material worth handling from which to obtain the Foraminifera found in the chalk in a condition almost, if not quite, uninjured, is the powdery matter found in the cavities of the flints which abound in the chalk, but especially in cavities in the large nodules known as " Paramondras "—masses of flint of very irregular ovoid form in which are cavities of various sizes filled with chalk containing Foraminifera, which as a rule are in fine preservation.

On no account should the plan be adopted of shaking up the powder with water in a bottle, which is worse than useless ; but if it is dry, the first thing is to sift it through a rather coarse sieve—zinc perforated with holes $\frac{1}{16}$ inch in diameter will do—so as to remove all the fine flakes of flint, which would cut gauze like lancets. If damp or wet, the powder may be *washed through* this zinc sieve under the tap into a sieve (9 inches in diameter and 4 inches deep), with Miller's silk-gauze 180 threads to the inch. Either way will answer well, but after much experimenting Mr. Elcock prefers first to dry perfectly and sift dry. What will not pass through this zinc sieve must be well and carefully washed, and looked over when dry, as it will contain

---

* Journ. Post. Micr. Soc., i. (1882) pp. 139–45.

† First paper (on recent Foraminifera) loc. cit., pp. 25-9. Cf. this Journal, *ante*, p. 436.

the largest forms, some of which, as *Nodosaria, Dentalina*, &c., may be nearly half-an-inch long.

A large cup-full of the fine sifted powder must now be put into the silk-gauze sieve, and a good stream of clear fresh water be allowed to wash it until all signs of milkiness have disappeared, and the water runs away quite clear, neither fingers nor spoon being used to stir up the material, but letting the stream of water from an indiarubber tube fixed to the water supply do all the work, directing it so as to move the powder well about. When the water runs away clear, wash all into a corner of the sieve, drain, and tip out the chalk powder on to a plate to dry *thoroughly* in the oven. Repeat this process until all is washed; and when dry and cold sift into sizes for examination. The finest siftings will probably be the richest in species. If the chalk-powder is good and the washing properly done, a considerable portion will be found to consist of Foraminifera, Ostracoda, sponge, and other spicules, the remainder being sand, &c.

If sponge spicules or other siliceous organisms only are being sought for, pour dilute hydrochloric acid over the chalk-powder, and let it remain for a day or two to remove all the lime; after which pour off the acid, and wash well with clean water until every trace of the acid is removed; then dry, sift, and examine.

As these Foraminifera are fossil and mostly siliceous they will not "float," but the washed material must after drying be examined under the Microscope and the individual shells picked out with a fine miniature red sable pencil, and for doing which there is no royal road. The best tray for the purpose is one made of black ferrotype plate 4 inches $\times$ 1½ inch with the edges on each side and one of the ends neatly turned up about $\frac{1}{16}$ inch, on which a layer of the washed material is spread as thinly as possible, and the tray passed regularly from right to left across the field.

Directions are also given for dealing with fresh dredgings of sea-mud, shore-mud, &c., and with ship's soundings, where the Foraminifera are mixed with tallow, lard, &c.

Of all ways of mounting Foraminifera none is to be compared with mounting them as opaque; they look best without a cover-glass. Ebonite rings should be selected of such sizes that one will just fit inside the other, the smaller being cemented to the slide and the larger to the cover-glass.

Preparation of Diatoms.*—Prof. J. Brun describes the following process which he employs for destroying the endochrome of diatoms.

If the diatoms are fresh and wet, crystals of permanganate of potash should be added, and 10 parts water for each 1 part of the salt. If the diatoms are dry (pure or mixed) they should be wetted with a little of the concentrated solution of the salt, having even crystals in excess. The reaction of the permanganate should last about 12 hours.

The mixture (placed in a 100 gr. phial) should be stirred occasionally and put in the sun or on a warm stove. The phial should

---

* Journ. de Microgr., vi. (1882) pp. 457-8.

then be half filled with water and $0 \cdot 50$ cgr. of calcined magnesia added and left to act for 2 or 3 hours, shaking it now and then. Pure hydrochloric acid is then added in 1 gramme doses every 10 minutes, and when the contents of the phial are colourless the operation is completed. To facilitate the reaction the phial may be plunged in warm or boiling water. The absolute purity of the distilled water to be used for the subsequent washings is an essential condition of success.

In this process we have first the energetic oxidization of the endochrome by the permanganate, then, by means of the acid, there is a disengagement of oxygen (or combustion), and finally the disengagement of chlorine which bleaches. It is to these successive reactions inside and outside the valves, to which must be attributed the perfect cleansing of their silex. By this treatment the delicate species are not corroded, particularly if, before the action of the acid, enough water is added.

The surfaces of the valves will be found to have lost all their coleacterine, and the minuter details, striæ or dots, clearly shown. The author has tried all the different physical and chemical processes which have hitherto been announced, and he has found none which succeed so completely and so regularly.

Mr. Kitton writes * that whilst theoretically the method appears to be a good one he fears that it will not prove so effective, when much vegetable or animal matter is present, as the old sulphuric acid and chloride of potash process.

Mounting Sections in Series.—The use of shellac † for fixing sections on the slide, introduced by Dr. W. Giesbrecht, is a very valuable addition to histological methods, as hundreds of small sections may be arranged in serial order, and all inclosed in balsam under the same cover without danger of disarrangement. The method is further extremely useful in mounting larger sections, particularly those composed of loose parts, or parts liable to swim apart.

The shellac is prepared and used in the following manner:—One part of bleached shellac ‡ is mixed with ten parts absolute alcohol, and filtered. The slide is first warmed to about $50°$ C., and then a thin film of the shellac laid on by a glass rod drawn once over its surface. Before using, the slide is again warmed, and the shellac surface washed with oil of cloves for the purpose of softening it.§

---

* Sci.-Gossip, 1882, p. 257.

† MT. Zoolog. Station Neapel, 1881, p. 184. Cf. C. O. Whitman in Amer. Natural., xvi. (1882) pp. 783–4. Also this Journal, i. (1881) pp. 953–4.

‡ Dr. Mark uses the bleached shellac in the form in which it is prepared for artists as a " fixative " for charcoal pictures. It is perfectly transparent, and a film of it cannot be detected unless the surface is scratched. He attaches a small label to the corner of the slide, which serves for the number of the slide and the order of the sections, and at the same time marks the shellac side (otherwise not distinguishable).

§ Cf. this Journal, i. (1881) p. 953, where the following direction is given :— " Before commencing cutting, brush over the shellac layer very thinly with creosote, and then lay the section upon it with as little paraffin as possible."

The wash is made with a small brush drawn backwards and forwards until the entire surface has been moderately but evenly wetted with the oil.

Sections are now cut and arranged for the first cover; this done, the slide is warmed over a spirit-lamp so that the paraffin adhering to the sections melts and flows together, forming an even layer, which cools almost instantly, and thus secures the position of the sections while those of the second cover are prepared. The sections for the last cover having been completed, the slide is warmed for ten minutes on a water bath, in order that the sections may sink into the shellac and become fixed, and the oil of cloves evaporate. After allowing the slide to cool the process is concluded by washing away the paraffin with turpentine, and mounting in balsam dissolved in chloroform.

The following mode of fixing sections is described by Dr. J. Gaule[*]:—

The sections are cut dry and placed on the slide in the order and position in which they are to be mounted.

They are then smoothed out by the aid of a fine brush wetted in 50–60 per cent. alcohol, until all wrinkles are removed and every part is in close contact with the slide.

The slide is allowed to stand several hours (or over night) until the alcohol has completely evaporated, and the sections are left adhering quite firmly to the glass. The process may be hastened by gently warming to 45–50° C.

The paraffin may be removed by any of the solvents in common use, but xylol is recommended. A few drops are allowed to flow over the sections, and after a few moments the paraffin is fully dissolved.

The balsam (a mixture of balsam and xylol in equal parts) is placed on the cover-glass, and this allowed to sink slowly, from one side, over the sections.

Dr. Gaule finds it convenient, especially with serial sections, to use large cover glasses—often nearly as large as the slide itself. Thus a single slide may often contain a large number of sections closely arranged under one cover.

For large sections this method offers one important advantage over that of Dr. Giesbrecht; by the former all wrinkles may be removed, while by the latter the sections must lie as they fall. In the case of smaller sections, not liable to get wrinkled during the placing, Mr. Whitman [†] prefers the shellac method.

Eau de Javelle for Removing the Soft Parts of Preparations.[‡] —Dr. F. C. Noll has found eau de javelle (subchloride of potassium $KC2O$) very suitable for preparations of *Spongilla*, and for destroying the protoplasm in other objects.

If siliceous sponges are burnt or boiled in potash the hard parts, spicules, &c., separate, and are not shown in their proper

[*] Arch. f. Anat. u. Phys., 1881, Phys. Abthlg., p. 156. Cf. also this Journal, *ante*, p. 428.
[†] Loc. cit.   [‡] Zool. Anzeig., v. (1882) pp. 528–30.

connection. To remedy this a piece of the sponge is placed on a slide covered with some drops of eau de javelle and left to stand with a glass over it, until all the soft parts are dissolved, which, in the case of thin sections, does not take more than 20–30 minutes. Gemmules take a longer time and should be left over night; their contents are dissolved without destroying the outer coat.

When the protoplasm is all dissolved the object is carefully treated with acetic acid which removes all precipitated matters, then with weak and afterwards with absolute alcohol. Finally oil of cloves (which in 15 minutes completely clears any cloudy gemmules) prepares the way for mounting in Canada balsam. The gemmules of *Spongilla fluviatilis*, *S. Lieberkühnii*, and *S. contecta*, from specimens which spread out on the under side of stones, remain *in situ* between the spicules, and give a perfect representation of the form of the sponge. In the more compact sponges, such as the free growing specimens of *S. Lieberkühnii*, the spicules remain united to the framework, although the lining and cementing substance has been dissolved. The layer by which the sponge is attached to its support, like the membrane of the gemmules, is not destroyed; it is not, however, turned black, like the latter, with a solution of nitrate of silver. These three elements of *Spongilla* have, therefore, a different chemical composition.

Diatoms are often found in the tissues of sponges, and these are as well prepared by the above process as they are after burning or boiling with sulphuric acid, so that eau de javelle is to be recommended as a very useful reagent for diatoms also.

To ascertain the effect on calcareous forms small mussel or snail shells (with or without epidermis) were laid in eau de javelle. They were clean and partly colourless but their lime remained uninjured. The same was the case with the calcareous bodies from the crust of different Gorgonidæ.

Small skeletons can be cleaned of skin, muscle, &c., without injuring the bones.

The liquid is also admirably adapted for cleaning vegetable sections. Potash and glycerine swell up the cell-walls or break up the preparations. In a quarter of an hour the sections are freed from all the soft parts and show only the clear cell-walls. After treatment with acetic acid they are mounted in Mayer's fluid (glycerine 1 vol., distilled water 2 vols., and to 10 vols. of this mixture 1 part salicyl-pyrogallic acid) or in gelatine-glycerine, balsam rendering the cell-walls too transparent.

Gum and Glycerine for Imbedding.*—L. Joliet has found that the soap which he was in the habit of using for imbedding, and which succeeded perfectly with the *Salpæ*, gave very bad results with *Pyrosoma*. It did not penetrate the common transparent substance which envelopes all the ascidio-zoids, so that they were rapidly distorted, and could not be cut. The following combination has, however, been of the greatest use :—

* Arch. de Zool. Expér. et Gén., x. (1882) pp. xliii.–v.

Dissolve in a little water some very pure gum arabic, so as to obtain a liquid having the consistency of a thick syrup.* Pour a little into a watch-glass, so as not to quite fill it. Then add from six to ten drops of pure glycerine, and with a small stirrer carefully mix the gum with the glycerine until it forms a homogeneous mass. Then lay the preparations on the surface of the liquid, and with needles press them into it.

This done leave the whole to dry, which takes from one to four days, according to the condition of the air. The gum will assume the consistency of cartilage; without being soft it is supple and yields to the finger. The cake of gum is then cut into squares or strips, corresponding with the preparations, and removed. A plate of gum enclosing the preparations is thus detached without difficulty from the bottom of the watch-glass. These plates are turned over and again allowed to dry until they are wanted for use; they may be preserved in good condition almost indefinitely, the gum, when mixed with a sufficient quantity of glycerine, never becoming hard or brittle.

The following are points to be noted:—Between the limits of 6 to 10 drops of glycerine above mentioned, the proportions most suitable to the nature of the object under examination and to the season of the year may be found by experimental trials. Too much glycerine prevents the gum from acquiring sufficient toughness, too little allows it to become brittle. In the winter or in rainy weather less glycerine should be added than in the summer or in dry weather. It is often well to soak the object in glycerine before putting it into the gum; the quantity of glycerine thus absorbed by the object being taken into consideration, and less added directly to the gum.

With a stove or by the help of the sun the gum can be very quickly dried, but in most cases it is a question of patience. It is one of the great advantages of the gum and glycerine that they dry so gradually; they are generally liquid the first day, pasty the second, and cartilaginous the third. The object having remained in this liquid for twenty-four hours is perfectly soaked, the gum having penetrated into all the interstices of the cells and the sections preserve the relations of organs which are not directly connected. With soap or gelatine the imbibition is in many cases less perfect, because, unless a high temperature is maintained for a long time, the solidification of the mass takes place too quickly and does not allow the liquid to penetrate so deeply into the tissues.

When the strips are removed from the watch-glass, it is better to wait until they have assumed such a consistency that they cannot be easily bent. It is after having waited almost a week that the author has always obtained the best sections.

Gum alone rapidly becomes hard and brittle; the effect of the glycerine is to preserve it almost indefinitely in a cartilaginous consistency. Another advantage of the method is the perfect transparency of the substance surrounding the object to be cut, so that it

* Solutions of gum, sold under the name of strong white liquid glue, may also be used. They have the advantage of having a uniform consistency.

is easy to examine the preparation under the Microscope before cutting ; the smallest details can be distinguished, and with a low power the object can be arranged very accurately, and the section can be made exactly through the desired point.

The sections being thus made, they are placed on a glass or a very dry surface, then taken up with a needle or fine moist brush and placed on the slide in a drop of water; the gum dissolves and leaves the preparation in place. A drop of glycerine placed at a corner of the cover-glass, quickly penetrates under it and replaces the water (which evaporates), and mixing with the melted gum, forms an excellent preserving liquid.

Roy's Microtome.[*] — Dr. C. S. Roy describes a microtome (Fig. 163) for cutting frozen or otherwise hardened substances.

The knife h is connected with the metal bar c by the clamp g.   A small piece of leather laid on the back of the knife at the place where it is held by g enables the section to be made at any desired angle to

FIG. 163.
the horizontal. By a handle n the bar c can be moved on the pivot e furnished with the milled head f. The pivot passes through the support b which is attached to the base plate a. The knife is thus able to move over the object plate d, describing a circle on the pivot e. The object plate may be raised or lowered by k, and its under surface is deeply fluted, with the object of diminishing the thickness of the

* Arch. f. Mikr. Anat., xix. (1881) pp. 137–43 (1 pl.).

metal, and increasing the surface exposed to the ether-spray, which is applied by an arrangement of tubes supported by a rod l. The plate is large enough for pieces of tissue from 4 to 5 mm. by $2\frac{1}{2}$ mm. downwards.

General directions are added as to freezing and cutting which it is unnecessary to repeat here. Specimens otherwise hardened, however, Dr. Roy prefers to imbed in a mixture of wax and olive-oil shaped to fit in the frame (Fig. 164), which is made by removing the plate d and adding a third vertical plate c, which is fixed by the screws b. A spring presses the plate e forward so as to prevent any lateral movement of the imbedding mass. The microtome is fixed to the table by a clamp with a screw the head of which is seen at m.

Dr. Roy adds subsequently * that the essential points for which he claims novelty in this microtome are the peculiar structure of the object-plate to increase the surface exposed to the ether spray, and the improvement in the manner of attaching the knife.

Professor C. Weigert,† in preference to the English razor, employs the knives made by Härtel of Breslau or Frank of Leipzig, for making the sections, as having a perfectly level surface and not rubbing with the lower surface the object which is cut. By applying the sliding principle of the Rivet microtome he avoids the *pressing* action of the razor which, for soft specimens, is so undesirable—a *drawing* motion being thus substituted. He diminishes the area of the plate over which the razor travels by bending its sides somewhat down. When using the sliding principle the objects must not be frozen too hard. When sections have been made by the freezing plan they are examined fresh or in salt solution.

Boecker's Microtome with Automatic Knife-Carrier.‡—Although the microtome has now reached a high degree of perfection (writes E. Boecker) many defects still exist in the usual forms, as well as in those with sliding carriers for the knife. For this reason, perhaps, many still prefer free-hand cutting with the razor, although it is scarcely necessary to remark how little accuracy can be thereby obtained, and what inferior sections of often valuable material are turned out. The principal fault of the microtomes hitherto constructed, consists in the frequent tearing of cells or tissues, caused— at least in slide microtomes—by the fact that the knife is often wrongly placed and having only a forward movement, presses the object rather than cuts it. It is at least expected of a good microtome that with careful manipulation not a single section should be lost, a requirement of the utmost importance in series sections, or in
* Arch. f. Mikr. Anat., xix. (1881) pp. 527-8.
† Arch. Path. Anat. u. Physiol. (Virchow), lxxxiv. (1881) pp. 287-90.
‡ Zeitschr. f. Instrumentenk., ii. (1882) pp. 209-12 (4 figs.).

rare pathological injections, so that it should be possible to make extraordinarily thin sections without the least tearing of the cells or tissues. How far the thinness of the sections can be carried is, of course, different in different objects, and it is therefore difficult to lay down any hard and fast rules.

For the fulfilment of these requirements Boecker first endeavoured

FIG. 165.
to give to the knife the proper movement, so that it should move in the same way as if guided by the hand. It appeared to him that the ordinary method of moving the knife by means of a slide was not sufficiently firm, and involved the inconvenience of keeping the slide steady by the hand. He also decided to give the knife such a considerable inclination that it should be nearly parallel with the direction of the slide.

This attempt was successful in every respect. Two slides of brass-plate are connected in such a manner that their movements shall cross at right angles. If the one slide S' (Fig. 165) is moved

longitudinally it must at the same time push the other slide S to the side. For this purpose S′ is provided with an oblique slit, in which the tube h slides backwards and forwards. The latter is attached to the plate a. The cylinder r serves for the reception of the object to be cut, and by means of the micrometer screw can be raised by hundredth parts of a millimetre, for which purpose a scale b with index d is added. The slide S has also a transverse slit, so that it does not come in contact with the tube h, and can move freely to a certain distance. The attachment for the knife is on the slide S′; the stability of the knife m is ensured by securing it in two places, first to the angle-piece k, which can be clamped in any position, and with the slide S′; and secondly by means of the screw $m′$ which, with the piece belonging to it, moves in a slit as shown in the figure.

The slide S′ is moved by the handle g, and the oblique slit enclosing the tube h (see Fig. 166) causes the slide S to move in the

FIG. 166.
FIG. 167.
direction $a\ a′$, and thus effects a "drawing" movement of the knife. This movement is uniform if the slit is straight, as in the figure, and it can be effected quicker or slower according as the slit is more or less oblique. The drawing movement can also be accelerated during the cutting process; but in this case the slit must have a curved form, as in Fig. 167. The whole microtome must, however, be broader, although at the same time it may be shorter. By this arrangement the knife is able to cut in any oblique position.

In the microtome described the cylinder has a diameter of 25 mm., amply sufficient in most cases, but capable of being increased. For cases where it is preferred to use the knife with the hand, a circular glass plate is added to the slide S′.

Staining Bacillus tuberculosis.*—We have already described Dr. Koch's original process for detecting this *Bacillus* and Dr. Ehrlich's improvement upon it, as well as that of Dr. Van Ermengem.† Dr. H. Gibbes, referring to the unsatisfactory nature of the first two processes, says that the following simple process will bring out the bacillus with ease and certainty. It takes but a short time to carry

out, and the bacillus is stained so deeply and differentiated so fully from the surrounding substance that it can be seen with the greatest ease with an ordinary $\frac{1}{4}$-inch object-glass and daylight, the previous processes having stained it so faintly that high power or artificial illumination were required. The colours used are magenta crystals, which stain the bacillus, and chrysoidin, which stains only the surrounding substance. It is a brown which does not stain so intensely as vesuvin. The formulæ are:—

Magenta crystals	..	..	..	..	2 grammes.
Pure aniline	..	..	..	..	3 ,,
Alcohol (sp. gr. ·830)	..	..	..	..	20 ccm.
Distilled water ..	..	..	..	..	20 ccm.

Dissolve the aniline in the spirit, rub up the magenta in a glass mortar, adding the spirit gradually until it is all dissolved, then add the water slowly, while stirring, and keep in a stoppered bottle.

Make a saturated solution of chrysoidin in distilled water and add a crystal of thymol, dissolved in a little absolute alcohol, to make it keep; a dilute solution of nitric acid (coml.) is also required, one part of acid to two of distilled water.

The object of the process is to stain the sputum, or section, as the case may be, with a colour which the dilute nitric acid will remove from everything but the tubercle bacillus, and the subsequent staining with chrysoidin is only required to throw up the stained bacillus and make it more prominent. In Dr. Ehrlich's process, the stain for the bacillus is too faint, and the vesuvin, used to stain the ground substance, too opaque; consequently the bacillus appears a faint pink colour on a dense yellowish brown ground, and is not easily made out without high power or special illumination. His method of dissolving aniline in water, in which it is very sparingly soluble, is also open to objection, as it is very apt to vary in the amount taken up by the water.

For sputum the following process is the most simple. Spread a thin layer on a cover-glass and let it dry; when quite dry pass it two or three times through the flame of a small Bunsen burner and let it cool. Filter two or three drops of magenta solution in a watch-glass, place the cover-glass with the sputum downwards on the stain, taking care there are no air bubbles under it. Let it remain for fifteen or twenty minutes, then wash in the dilute acid until all colour has disappeared, remove the acid with distilled water, when a faint colour will return; then place the cover-glass in the same manner as before on a few drops of chrysoidin filtered into the bottom of a watch-glass, and let it remain a few minutes until it has taken on the brown stain; wash off the superfluous colour in distilled water and place the cover-glass in absolute alcohol for a few minutes, remove and dry perfectly in the air, place a drop of Canada balsam solution on the cover-glass and mount. It is better to use small glass funnels for filtering the stains, as they protect the fingers. Sections of hardened tissue are treated in the same manner with the necessary modifications.

With regard to the powers required to examine the bacilli after

they have been mounted by this process, an ordinary $\frac{1}{4}$-inch with day-light will show them perfectly, and a $\frac{1}{8}$ dry glass will show that they are rows of spherical bodies with the same illumination.

OBITUARY.

The following Obituary notices were read by the President in his Address, *ante*, p. 145:—

CHAS. JOSEPH HYDE ALLEN, F.L.S., F.G.S., F.Z.S., was elected in 1859 and appointed Treasurer of the Society at the Annual Meeting in 1862, but failing health compelled him shortly afterwards to leave England. Mr. Allen died 20th March, 1881, aged 62.

SIR ANTONIO BRADY, KT., J.P., F.G.S., F.M.S., F.A.S.L. (elected in 1854, died 12th December, 1881), was the eldest son of the late Mr. Anthony Brady, of the Royal William Victualling Yard, Plymouth, by his marriage with Marianne, daughter of Mr. Francis Perigal. Born in 1811, he entered the Civil Service of the Navy as a junior clerk in the Victualling Yard, Deptford, more than fifty years since. After serving in various offices, he became head of the Contract Office and Registrar of Public Securities in 1854, subsequently assisting to reorganize that office. He was subsequently appointed first superintendent of the Purchase and Contract Department, retiring from the service in 1870, when he received the honour of knighthood. After his retirement, Sir Antonio took a leading part in the preser-

vation of Epping Forest for the people, and was appointed a judge in the " Verderer's Court for the Forest of Epping." He was a great and able collector of the osseous remains of the great post-pliocene mammalia, and was a member of the Geological and other Societies. He married, in 1837, Maria, eldest daughter of the late Mr. George Kelner, of Ipswich, by whom he leaves a son, the Rev. Nicholas Brady, M.A., and two daughters.

RICHARD CLEWIN GRIFFITH, M.R.C.S., F.R.G.S., F.Z.S., M.R.I. (elected in 1855, died 5th September, 1881), had at the time of his death attained the great age of ninety years (less three days). He passed his examinations in 1812 and 1813, and was among the first batch of "general practitioners." He took his father's practice, in Tottenham-court-road, then a country suburb of London, and after a few years removed to Gower-street. He is described as having " belonged to the old school of practical medicine, and despised theories." He was the father of the Apothecaries' Society, of which company he was the Master about twenty-six years ago. For several years the late Mr. Charles Brooke, of the Westminster Hospital, was his partner.

WILLIAM MOGINIE (elected 1866, died 13th December, 1881, aged 53). Mr. Moginie from early youth took great interest in microscopical and other scientific pursuits, and as an amateur was one of the first to produce micro-photographs, some of which have never been surpassed. He also made several improvements in the instrument, the chief being the ' Moginie Travelling Microscope,' one of the most convenient of portable Microscopes. Besides being well known as a practical optician, possessed of great mechanical ingenuity, Mr. Moginie was especially noted as a demonstrator, there being few who could exhibit an object with equal skill as regards definition and illumination. Microscopists have lost a prominent and valued member, and his considerable circle of acquaintances a kind and warm friend.

JAMES TENNANT, F.G.S., F.C.S., F.M.S., F.Z.S., was one of the original Members of the Society, having been elected in 1840. He was for many years Professor of Geology and Mineralogy in King's College, London, and subsequently held the Mineralogical chair. He was Mineralogist to the Queen, and a Fellow of many of the learned societies, and was highly appreciated as a mineralogist. He formed a large collection of minerals, and took a great interest in science generally, endeavouring to connect one of the City companies with the movement in favour of technical education.

PROCEEDINGS OF THE SOCIETY.

MEETING OF 11TH OCTOBER, 1882, AT KING'S COLLEGE, STRAND, W.C.,
THE PRESIDENT (PROFESSOR P. MARTIN DUNCAN, F.R.S.) IN
THE CHAIR.

The Minutes of the Meeting of 14th June last were read and
confirmed, and were signed by the President.

The List of Donations (exclusive of exchanges and reprints)
received since the last meeting was submitted, and the thanks of the
Society given to the donors.

	From
Dippel, L.—Das Mikroskop, &c. 1er Theil, 1e Abtheil. 2nd ed., viii. and 336 pp. and 189 figs. (8vo. Braunschweig, 1882)	*The Author.*
Dodel-Port, A. and C.—Anatomisch-physiologischer Atlas der Botanik. Part 6	*The Authors.*
English, J. L.—A Manual for the Preservation of the larger Fungi, &c. viii. and 41 pp. (8vo. Epping, 1882) ..	*Mr. Crisp.*
Micrographic Dictionary. 4th ed. Parts 13–15	*Mr. Van Voorst.*

Mr. Stewart called the special attention of the meeting to Dr.
Dodel-Port's diagrams (in continuation of the series), which were not
only executed with admirable effect, but were also exceedingly correct
and of great use for the purposes of the lecture-room.

Mr. Beck exhibited a slide of *Bacillus tuberculosis* prepared by
Dr. H. Gibbes by the new process he had devised (see p. 895).

Mr. Beck also exhibited and described a new " Lithological
Microscope " (see p. 847).

Mr. Stewart thought that whilst there were many admirable points
about the instrument, yet that, in use, the movement of the polarizing
prism might work loose in course of time through being on a hinge
joint, and he suggested that it would be found an improvement to have
an arrangement shifting in a plane parallel to the stage.

The President said that the subject which Mr. Beck's Microscope
was intended to facilitate—now known as Petrology—was a branch of
geology which was of extreme interest and importance, and which
had made gigantic strides in recent years, so that there were now
many geologists who confined their attention to the examination of
rock sections. In the course of such observations, the constant
shifting of the prisms was extremely tedious, and some remedy for
this was indispensable. The important question was, which of the
various methods was the easiest? In looking at the instrument as it
stood, he thought that the necessary movement could be effected more
easily as Mr. Beck had constructed it than by a lateral movement as
suggested by Mr. Stewart. This branch of geological study was, he
considered, a most desirable one for the Fellows to take up. It in-

volved a study of optics as well as of geology. There was an idea that such observations could be carried out better elsewhere than in this country, where they first originated; but he thought that, with the aid of Mr. Beck's improvements, there would be no difficulty in showing that we were able to investigate the subject, at least as well as could be done anywhere else.

Mr. Crisp exhibited and described (1) Gundlach's College Microscope (see p. 670); (2) Boecker's Air-Pump Microscope; (3) The Bausch and Lomb Optical Company's Immersion Illuminator (see p. 688) (the latter not, however, being 1·52 N.A. as marked, but about 1·20 N.A.); (4) Thomas' Vivarium (see p. 688); and (5) a new achromatic spherical pocket lens, by Gundlach ("Globe lens"), which consisted of a sphere of crown glass enclosed in an outer sphere of flint glass.

Mr. Ingpen described a method of rapidly attaching objectives to the nose-pieces of Microscopes which had been devised by Mr. E. M. Nelson, the idea having been suggested to him by the method employed by the French for fixing the head-pieces of ordnance (see p. 858).

Dr. Ondaatje, of Ceylon, was introduced to the meeting by the President, and exhibited and described a number of specimens of Echinoderms, Gorgonidæ, Algæ, &c., which he offered to the Fellows for mounting.

The President, in thanking Dr. Ondaatje for his communication, said that a small specimen of *Echinus* was especially curious, as it seemed to him it did not consist of the original carbonate of lime of the creature, but looked more like crystallized calcite, as if it had been concreted in some way.

Mr. E. W. Burgess's letter was read, accompanying specimens of diatoms from the Island of Lewis (see p. 665).

Mr. Crisp said it would be in the recollection of the Fellows that, at the April meeting of the Society (see p. 440), a note by Drs. Loew and Bokorny was read, as to the chemical difference between living and dead protoplasm, and that some remarks were made by Mr. Stewart as to the possibility of some of the effects being due to the remains of the citric acid used in killing the protoplasm. Dr. Loew had since written a note in reply to the criticisms, which was then read as follows :—

"I learn from the June number of your highly-esteemed journal that the discovery of a chemical difference between living and dead protoplasm by myself and Bokorny has given rise to some discussion in the Society. Mr. Stewart has expressed some doubts in regard to our statement, believing that some residual citric acid (which we had applied in one case of killing the cells) might have been the cause that no silver was reduced.

In regard to this I have to say that the acid was removed as well as possible by continued washing with distilled water, before applying the silver reagent. Besides, the *alkaline* nature of the latter would have neutralized any trace of the acid left. The reason why, after killing with citric acid, no more silver was reduced by the cells, was certainly a chemical change of the protoplasm itself.

Whoever will take the trouble to study our publication, 'Die Chemische Kraftquelle im lebenden Protoplasma (The Chemical Source of Power in the living Protoplasm), will find that every precaution was taken in all our labours to avoid errors and false conclusions. We have killed the cells in all possible ways: by starvation, by desiccation, by heating to 50° C., by mechanical action, by electrical sparks, by ether, alcohol, carbonic acid, kerosene, sulphuretted hydrogen, by sugar, tannin, by acids, alkalies, and salts; and in all these cases the protoplasm had become changed, so as to be incapable of reducing silver. In one case, however, death was produced by destruction of the structure and organization *alone*, the chemical nature remaining unchanged; it was by the action of certain poisons, especially alkaloids. We have described these cases in minute detail in our publication.

Life must be considered as the result of two functions :—

1. Of a specific chemical motion—viz. the energy of the aldehydic groups in the molecule of the *active* albumen.

2. Of the organization of the protoplasm—viz. the specific molecular construction from molecules of active albumen. If *one* of these functions is destroyed, death is the result (see pp. 25 and 77 of our publication).

No thinking mind will doubt that the vital force is a mode of motion, like all other forces of nature. We have proved beyond a doubt that the vital force is the result of a specific *chemical* motion, as minutely explained in our publication (see pp. 19–25 and 88).

It is true there are many objects which are so sensitive, that they die too quickly to give the silver reaction, which is only slowly developed, requiring many hours; we have described such cases too (see pp. 60–62 of our publication).

I have proved, furthermore, that the *quantity* of reduced silver corresponds with my theory (see pp. 91, 92), and have arranged now to analyze the product formed by the action of the silver solution upon the living protoplasm; a product that it is impossible to obtain with dead protoplasm.

In regard to Mr. Stewart's remarks on 'silver-staining,' it is most essential to note that the silver-staining process is based *upon the action of light*; many organic substances will reduce silver, *if in contact with light*. Our process, however, goes on in absolute darkness! and is quite a different thing from the 'silver-staining process.'

Recently some volatile aldehydes have been discovered in plants by Mori and by Reinke; but we must utterly deny that our observation has anything to do with such an aldehyde. Our objects were entirely free from any volatile or soluble aldehyde; hence our reaction shows conclusively *the aldehydic groups as constituent parts of the molecule of active albumen*. The albumen, passing from the active

into the passive condition, loses the *aldehydic groups* by displacement of the atoms ('Atomumlegerung') and the intense chemical motion has ceased herewith at once."

Mr. Stewart said that the remarks which he made on the occasion referred to were hardly offered as a matter of criticism, but rather by way of inquiry. It was clear that the experiments of the authors had been conducted with singular precision, and he was very glad that his observations had been the means of bringing out these additional particulars. He might also say that the original paper of Drs. Loew and Bokorny having been sent to him, he had laid it before Dr. Bernays, the chemical lecturer at St. Thomas's Hospital, who had been so much interested in the subject that he intended to thoroughly investigate it, and no doubt they would in due course hear the results of his experiments. Meanwhile, as a preliminary, he had received from him the following letter:—

" I have read the letter of Drs. Loew and Bokorny, and consider as proved by them that the power of producing alkaline silver solutions is an essential property of many forms of living vegetable plasma. I consider that a complete answer is furnished to your own suggestion about residual citric acid: that must be given up. The experiments of Drs. Loew and Bokorny have been made with a care and skill deserving of the highest praise.

Of the nature of animal protoplasm little is known. The authors of 'Die Chemische Kraftquelle im lebenden Protoplasma' admit as much; but they consider themselves entitled to the judgment that the reactions of aldehyde groups in active albumen are capable of equal application. The cases of chronic silver-poisoning do not seem to confirm the view, as we should certainly expect on the aldehydic theory a much more even distribution of metallic silver. And, in the case of man, alcoholic potations would have to be rigidly excluded in order to *assist* in the confirmation, or otherwise, of the aldehydic theory. Whether any, and what, differences exist between vegetal and animal albumens we cannot exactly say.

The aldehydic theory is the most interesting attempt at explaining the distinction between living and dead protoplasm that has ever been offered. But, although the reactions discovered by Drs. Loew and Bokorny are similar, *in the one aspect of reducing alkaline silver solutions*, I do not see more in their most interesting statements of experiments and views than to confirm most successfully the difference between living and dead plasma. For myself, I say, with all deference to these distinguished scientists, that further proof must be offered of the view these gentlemen hold, before I would accept the aldehydic theory as more than an interesting attempt at explanation."

Mr. **Crisp** read a note from Mr. C. Stodder as to the Tolles $\frac{1}{4}$-inch objective with tapering front, exhibited at the June meeting (see p. 589), in which the writer pointed out that the speakers at that meeting, who stated that "similarly tapered" objectives had been made as early as 1848 by Andrew Ross, and since by others, had not understood "the peculiarity or the purpose of the construction of the

objective exhibited. It is not merely an objective of the usual form in a tapering or conical brass mount, but the front lens is itself a cone." No such objective had ever been seen in America previously to that first made by Tolles in May 1870, and there is no record of any having been made in England or anywhere else.

Mr. Ingpen said he was now able to exhibit the objective he referred to at the last meeting by Andrew Ross. Its aperture was 60°, and the front lens, which was a triplet $\frac{3}{10}$ inch in diameter, was coned down to an angle of 120°, reducing the front to $\frac{1}{10}$ inch surface. Opaque objects could be illuminated at an angle of 30° from the level of the slide. The primary reason for coning this particular objective was the use of a very narrow Lieberkühn, but objectives were also coned for the purpose of getting rid of "stray light," to which particular attention was afterwards called in an article by Mr. Wenham on angular aperture, published in 1874, after which many lenses were coned for that purpose. The practice had since been to a great extent abandoned, in consequence of the reduction of aperture caused by it.

Mr. Beck said it was quite preposterous for any one to suggest that there was any novelty whatever about the objective referred to by Mr. Stodder. James Smith, who was a very skilful worker in glass, used to pride himself upon the way in which he was in the habit of coning down object-glasses. He used to fit them in a cell, and then turned them down in a lathe with a diamond, so that the front lens had no cell at all. A small brass cap was fitted over it to prevent any danger of its being injured.

Dr. Edmunds said that the Fellows always cordially welcomed communications from foreign microscopists. It was true that it had been demonstrated this evening that the idea of coning off the front lens of an objective had been tried long since by English opticians, and therefore that the plan communicated by Mr. Stodder was not new; but he thought Mr. Tolles was evidently entitled to the merit of an independent invention. These discussions over devices tried and lost sight of, only to be reinvented a generation later, showed the value of the figures and technical descriptions of apparatus which had been published in the Society's Journal of late years. He asked if Mr. Beck or Mr. Ingpen could give the meeting any references to previous descriptions of the method.

Mr. Beck said it was recorded in the catalogues of their firm; and if any other evidence was needed, it might be found in the fact that a large number of microscopists were in possession of similar objectives. Mr. Beck then examined the Society's Cabinet, and produced one of James Smith's objectives, made before 1847, the front lens of which was coned off in the manner described, and a small cap put over it.

Mr. J. Mayall, jun., said he understood Mr. Stodder's claim on behalf of Mr. Tolles to be that he originated the plan of reducing the front lens or lenses of an objective, as near as possible to the cone of light transmitted, so that the exposed surface of the front lens was the exact working diameter required for the aperture of the whole combination. By such acute coning no doubt the greatest range was

provided for the use of Lieberkühns, &c.   He had examined many low-power objectives with tapering fronts, but the great majority were seen at a glance to have been coned with no other purpose in view than to improve their appearance.   With regard to the Ross $\frac{1}{2}$-inch objective of 60° air-angle, exhibited by Mr. Ingpen, of which the body of the front lens was coned to an angle of 120°, it was evidently not Andrew Ross's intention to cone the front to the uttermost, or he would have cut it down to an angle of about 40° instead of 120°: 40° in the body of the crown-glass front being sufficient to transmit a pencil of 60° from air.   Could Mr. Beck affirm that the objective he referred to, made before 1847, was coned in front so as to allow just the full aperture to be utilized?   If so, he (Mr. Mayall) thought Mr. Stodder's case must fall to the ground.

Mr. Beck said that the one he held in his hand was done with the precise object of getting the front reduced to the smallest cone possible.

————————

Dr. Dippel's note " Correction-Adjustment for Homogeneous-Immersion Objectives," was read by Mr. Crisp (see p. 854).

Mr. Beck said that the paper seemed to him to be an apology for being content with inferior definition rather than taking the trouble to get the best that was to be obtained.   He understood the course of argument to be that there was so much trouble in making the adjustment that it was better to do without it.   He ventured to say that there was not any one who had got over the trouble who would for a moment put up with what was inferior, if he had it in his power to get what was the better.   He should like to hear some observations on this subject from Mr. Mayall.

Mr. Crisp said that the author of the paper did not put the matter on the ground of trouble at all.   What he said was that the advantages to be derived from the adjustment-collar were so infinitesimal in the case of unknown objects, that they did not compensate for the disadvantages.

Mr. Ingpen thought that even amongst those who were thoroughly familiar with the use of the highest powers, very few would be found capable of adjusting an objective to the same degree of accuracy as the optician, and therefore any one who had a valuable objective should be very careful not to disturb its correction.   It was also, he believed, a matter of experience that with the particular class of objects referred to by Dr. Dippel, no two histological observers would agree as to the best correction. Professor Abbe had met that difficulty by proposing a special test-object for the purpose, and as the description of this method would, he understood, shortly appear in the Journal, he need not enter further into that part of the subject, except to say that the Professor's test-plate was not like the *Podura* scale or *P. angulatum,* but showed beyond question what the best correction was, and made it possible for a person to pass a number of objects under the objective, and at once determine the best correction for each.

Mr. J. Mayall, jun., said he concurred in much that Mr. Beck had

said, especially in his advocacy of all that tended towards the perfection of objectives. As regarded the application of the correction-adjustment to homogeneous-immersion objectives, he was obliged to express his disagreement with Dr. Dippel. The facts on which his own judgment on this question was based were briefly these:—When Zeiss's homogeneous-immersion objectives were first sent to England, he immediately observed that certain dry objects, such as *Podura*, were very indifferently defined by the new lenses, precisely as he had previously found with water-immersions in fixed settings. These objects were always such as did not adhere very closely to the cover-glass. Knowing from experience that the correction-adjustment had, in many cases, met the difficulty with water-immersions, he took an early opportunity of pressing upon Messrs. Powell and Lealand to apply the adjustment to the homogeneous-immersions. The result fully answered his expectations. There could be no doubt whatever that the correction-adjustment increased the range of conditions within which the homogeneous-immersions would give fine definition. He might state, as a matter of repeated personal experience, that in testing a number of homogeneous-immersions—fixed settings *versus* adjustment settings—whilst there were undoubtedly many preparations which were defined equally well by both systems, there were also many upon which no superficial structure could be discerned with the objectives in fixed settings, but which yielded well-defined images when viewed with objectives having the correction-adjustment. The differences in the lenses might not be so marked as those seen in comparing dry lenses with and without adjustment; but still they were unmistakable, and unquestionably in favour of the adjustment. In the best homogeneous-immersion objectives he had examined, the corrections were so sensitive that different thicknesses of cover-glass had to be compensated for by the adjustment; whilst different specimens of oil of cedar-wood so completely altered the character of the image, that unless the correction-adjustment were brought into use, the objective might be condemned as defective. Even with the correction-adjustment, a marked variation from the normal immersion-fluid could not be compensated for. The objectives he here referred to were those of apertures from $1 \cdot 2$ to $1 \cdot 47$. He could not agree with Mr. Ingpen that it was best for the amateur to let the opticians choose for him the best average adjustment, and there fix the lens-mounting. He considered the amateur should make himself skilled in the use of the adjustment. As to the difficulty of finding two persons who would agree on the best point of adjustment in attempting to interpret an image of an histological preparation, he thought the solution of the difficulty would be best found by ensuring greater skill in making the preparation. When the *Bacillus tuberculosis* was first observed, it was only after great perseverance that anything could be interpreted from the confused mass of images; but the moment better methods of treating the preparations were found, the difficulties vanished, and what had formerly required hours of patient investigation to glimpse was now exposed to the eye at a glance. It would be interesting to the Society to learn that Prof. Abbe himself had so far wavered from his former opinion against the application of the cor-

rection-adjustment to homogeneous-immersions that he now agreed with Dr. Zeiss that those objectives should be supplied either with or without adjustment; accordingly, in future, both kinds would be supplied. He gave this on the authority of Dr. Zeiss. Prof. Abbe must therefore be regarded as partially, at least, opposed to Dr. Dippel's views. He might add that, among the opticians who were in favour of mounting homogeneous-immersions with correction-adjustment, were Powell and Lealand, Ross, Schroeder, Spencer, and Tolles.

Mr. Crisp said that Dr. Dippel did not dispute that a somewhat higher degree of accuracy might be obtained with the correction-collar, but it was only with known objects, such as the Abbe test-plate, and with the closest examination. With unknown objects, however, he considered it was utterly impossible to determine the position of best correction, and the correction-collar had, therefore, in those cases, no advantage to compensate for its disadvantages, and should not be used by histologists at any rate.

Mr. Crouch said that, in making the rough adjustments for students' Microscopes, they had to bear in mind the purposes for which they were likely to be used. In ordinary cases they would have to provide for histological sections, and this was not an easy matter, being quite unlike the case of a *Podura* scale, where they could adjust properly, because they had a surface to focus upon. He found the best average results were obtained from an objective when it was adjusted for an average thickness of cover-glass. He had known cases in which objectives with correction-collars had been condemned and returned to him, because it was said that good definition could not be got, the same objective being pronounced satisfactory after being remounted in a fixed setting.

Dr. Edmunds thought that adequate weight had not been given to the difficulty of ascertaining what was the true image of a complex histological section when viewed under a high-power objective. The real question was whether that image could be most certainly fixed upon by means of a lens furnished with a correction-collar, necessitating its adjustment for each object. Microscopists who devoted themselves to the resolution of *Amphipleura pellucida*, or of Nobert's lines, often knew nothing of the difficulty of interpreting the structure of muscular fibre and other more complex histological objects. The *Podura*-scale, though used as a test-object for histological lenses by their makers, yet was an object whose structure had never yet been interpreted in any way which commanded general assent. Take, again, *Pleurosigma formosum* in balsam, which presented different appearances with every touch of the correction-collar and with every variation in focal distance, so that it could not be interpreted with certainty; were a skilled microscopist now to see this object for the first time, a correction-collar upon his homogeneous lens would only add to his difficulties in fixing upon what was its true image. With a water-lens and varying thickness of cover-glass, the case was different, and the correction-collar was indispensable. While, therefore, the correction-collar might be theoretically an advantage, he thought that in practice it would be a disadvantage, and that, instead

of attempting to correct the objective, we should correct the object by mounting it always under conditions defined as those of homogeneous immersion.

Mr. Guimaraens called attention to a slide labelled "Pedicellariæ in situ, attached to the spine of *Echinus gracilis*," and sold as illustrating a discovery that pedicellariæ are attached to the spines of *Echini*. He would be glad to know whether the pedicellariæ in question were naturally attached to the spine, or whether an imposition had been practised.

Mr. Stewart said that in this specimen the pedicellariæ were undoubtedly adherent; but they could not have been so during the life of the animal.

The following Instruments, Objects, &c., were exhibited:—
Mr. Beck:—(1) Slide of *Bacillus tuberculosis* prepared by Dr. H. Gibbes. (2) New Lithological Microscope.

Mr. E. W. Burgess:—Diatoms from the Island of Lewis.

Mr. Crisp:—(1) Gundlach's College Microscope. (2) Boecker's Air-pump Microscope. (3) The Bausch and Lomb Optical Co.'s Immersion Illuminator. (4) Thomas's Vivarium. (5) New Achromatic Spherical Pocket-lens by Gundlach ("Globe lens").

Mr. Guimaraens:—Slide labelled "Pedicellariæ in situ attached to spine of *Echinus gracilis*."

Mr. Ingpen:—(1) Nelson's Nose-piece Adapter. (2) Objective of Andrew Ross with tapering front.

Drs. Loew and Bokorny:—Twelve slides illustrating their views on the chemical difference between dead and living protoplasm.

Dr. Ondaatje:—Specimens of Echinoderms, Gorgonidæ, Algæ, &c.

MEETING OF 8TH NOVEMBER, 1882, AT KING'S COLLEGE, STRAND,W.C., THE PRESIDENT (PROFESSOR P. MARTIN DUNCAN, F.R.S.) IN THE CHAIR.

The Minutes of the meeting of 11th October last were read and confirmed, and were signed by the President.

The List of Donations (exclusive of exchanges and reprints) received since the last meeting was submitted, and the thanks of the Society given to the donors.

	From
Braithwaite, R.—The British Moss Flora. Part 6	*The Author.*
Deby, J., and Kitton, F.—A Bibliography of the Microscope and Micrographic Studies, being a Catalogue of Books and Papers in the Library of J. Deby. Part 3. The Diatomaceæ	*Mr. Deby.*
Saurel, L.—Du Microscope au point de vue de ses applications à la connaissance et au traitement des Maladies Chirurgicales. 148 pp. (8vo. Paris, 1857)	*Mr. Crisp.*
Six slides of ovaries, &c., of plants	*Mr. Krutschnitt.*
Five slides of Diatoms mounted from the materials sent by Mr. W. F. Petterd from Tasmania	*Mr. Kitton.*

Mr. Collins exhibited a portable form of his histological Microscope, the special feature of which was the folding-up of the heel-piece of the tripod.

Mr. Curties exhibited several of Zeiss's pocket and dissecting microscopes.

Mr. Crisp exhibited and described (1) Guillemare's School Microscope (see p. 669) and (2) Prof. Abbe's Refractometer, for readily ascertaining the refractive index and dispersive power of fluids to be used for homogeneous immersion.

Mr. Krutschnitt's (New Orleans) six slides, four of which were sections of the ovaries of plants, were exhibited in support of the author's view of the fertilization of the ovule.

In the letter accompanying them, the writer said "the sections of the ovaries may go to show that the theory of the fertilization of the vegetable ovule by means of the pollen-tubes requires overhauling. See Amer. Mon. Micr. Journ., June 1882."

Dr. Maddox exhibited photographs of microscopical objects, printed by the platinotype process, which he found very suitable for scientific work, the paper being of fine texture, and capable of giving minute detail. (See Brit. Journ. of Photography, Sept. 15th, 1882.)

He also exhibited and described some new forms of warm and moist stages, which he exhibited in the room, and further explained by means of diagrams.

The President said that the stages were very simple, and very easily used, and would doubtless be of great use in examining blood and other objects, which it was desired to keep at an even, warm temperature.

Mr. J. W. Groves exhibited and described his improved ether-freezing microtome (see p. 755).

Mr. Stewart said that his own experience was that the ether method of freezing was a great advantage, for the full range of temperature was at command. It was only necessary to take care that the freezing was not overdone, so as to make the subjects brittle. A little practice enabled a person to control the temperature at will.

Mr. Kitton's note was read describing the results of his examination of the diatom material, sent by Mr. W. F. Petterd from Tasmania, which contained several interesting forms, but no new genera or species.

Mr. T. B. Rosseter's paper "Researches on the Life-history of *Stephanoceros Eichornii*," was read, and illustrated by drawings enlarged on the black-board.

Mr. Crisp said that the author of the paper was worthy of every possible encouragement and commendation, as his observations were

carried on under the greatest difficulties, and much credit was due to him for the indefatigable way in which he pursued them.

The President thought the paper was a very admirable one, whatever difference of opinion there might be as to some of the points touched upon.

Mr. T. C. White said that he was under the impression that as far as the attachment of the ovum to the parent was concerned, it was really attached to the case. The gelatinous envelope could hardly be called a case in the sense of being a thin structure, but it was rather a thick tube with solid walls, and when the creature retracted itself, the portion of the tube to which the ovum was attached was carried down with it. As regarded the viviparous character mentioned, he had observed it in *Rotifer vulgaris*, and had also noticed the fact that the parent died as Mr. Rosseter described.

Mr. Badcock having had an opportunity of previously reading the paper, read some critical remarks which he had written as to the question of the tube being " solid " or not.

Mr. Beck thought that the paper was an exceedingly interesting one, and after the remarks which had been made by Mr. Crisp as to the circumstances under which the observations had been made, it was doubly interesting. The way in which the writer had combined observation with experiment, and the manner in which he described the results, was, he thought, very creditable indeed. The fact of the creature making its way out of the cell, not at the top but at the lower end, was very interesting, for it would be natural to suppose that if any injury had taken place it would have escaped in the opposite direction. It occurred to him that this circumstance might afford a clue as to the way in which these objects expanded.

Mr. Michael thought that to a certain extent the question of an attachment to the tube was a substantial one, but whether the case was solid or tubular was more a matter of words. Pritchard could not mean that a cylinder in which a creature moved up and down was really " solid "; what he meant was probably that, instead of being a mere thin shell, it had a considerable thickness approaching towards solidity. The dragging down of the ovum, he thought, commenced before the arms touched the tube.

The President said it appeared to be quite clear that the tube had a considerable thickness, and that the attachment or adhesion to it was by the base only. With regard to the curious twisting round of the animal to get out at the lower end, it should be remembered that these creatures were *Vermes*, and that this was just the kind of thing a worm would do under the circumstances. He quite agreed with Mr. Beck in his remarks on the paper, and he hoped they would have more of the same kind.

Mr. Crisp made some remarks on the criticisms that had been passed on the paper.

Dr. **Maddox** read a paper on " Some Organisms found in the Excrement of the domestic Goat and the Goose " (see p. 749).

Mr. Geldart, the President of the Norfolk and Norwich Naturalists' Society, one of the *ex-officio* Fellows of the Society, was welcomed by the President.

Mr. Geldart said he was greatly obliged to the Fellows for the welcome given to him, and could only express the gratification which it afforded him to be present. He also wished to take advantage of the opportunity to thank them, in the name of his Society, for the privilege afforded to them of receiving the Journal of the Society, and profiting by the very admirable summary which it contained of all that was being done in microscopy, both at home and abroad.

Mr. Geldart then called attention to a slide of *Globigerina* which he had brought, with all its spines *in situ*—so unusual an object that it seemed to be worth bringing for exhibition. It was obtained by the 'Challenger.'

The President inquired whether it came from the surface.

Mr. Geldart said that this, and, indeed, all those, few in number, which had been obtained, came from the surface. Those brought up from the floor had the spines dragged off by the towing net. He had never seen more than two.

The President said that in examining some deposits from 14,000 feet he found them crammed with *Globigerinæ*, amongst which he had the good fortune to find one with spines. He was very glad to have seen this specimen as being an original from the 'Challenger' expedition.

The **Conversazione** was announced for the 6th December.

The following **Instruments, Objects, &c., were exhibited**:—

Mr. C. Collins :—Portable Histological Microscope.

Mr. Crisp :—(1) Guillemare's School Microscope.   (2) Abbe's Refractometer.

Mr. Curties :—Simple and Dissecting Microscopes by Zeiss.
